If $D_{m_G,s}$ is shorter than the length of the project crediting period, it means that the SOC will reach equilibrium during project implementation. The annual change in SOC occurring between the project start date and the time where SOC stocks reach equilibrium, $\Delta SOC_{m_G,s}$ can be calculated using Equation 43 and 44. For the period from the SOC stock reached equilibrium to the end of the project crediting period, $\Delta SOC_{m_G,s}$ and PR_t must be set to zero.

The applicability of the selected model and parameters recorded for the various activities, soil and climate types are dependent on the actual project. Since these are project specific and not methodology specific, they should be discussed in detail in the project document. However, data used to parameterize the selected model must be based on measurements of soil properties including bulk density and organic carbon concentrations to the full depth of affected soil layers, or a minimum depth of 30 cm where the full depth of affected soil layers is not known in advance.The required procedures for the sampling and measurement of these soil properties are outlined in Option 2 immediately below.

Option 2: Estimate of project removals due to changes in SOC using a measurement approach

For measuring soil organic carbon stock changes, soil sampling must follow a scientifically established method (eg, methods described in Carter and Gregoroch, 2006), or a nationally-approved standard (eg, the soil sampling protocol used to certify the changes of organic carbon stock in mineral soil of the European Union[5]). The frequency of SOC monitoring must be at least once every five years. Handling, storage, processing, measurement, and quality control of soil samples must follow scientifically established procedures such as the procedures described in Carter and Gregoroch, 2006, OECD, 1998, or nationally approved standards. Procedures should ensure that the presence of carbonates is adequately accounted for. Soil properties including bulk density and organic carbon concentration must be measured to the full depth of affected soil layers, or a minimum depth of 30 cm where the full depth of affected soil layers is not known in advance.

The below Equation 45 is used to calculate the SOC stock in stratum s, sampling site *i*, under project in year *t*. Sampling procedures should be designed such that the statistical significance of soil carbon stock changes between the baseline carbon stock and the carbon stock in time *t* can be determined with a 95 percent confidence interval. The *General Guidelines for Sampling and Surveys for Small-Scale CDM Project Activities* should be followed to determine the sampling procedure and sample size.

$$P_{SOC_{m_G,s,i,t}} = SOC_{m_G,s,i,t} \times BD_{m_G,s,i,t} \times Depth \times (1 - FC_{m_G,s,i,t}) \times 0.1 \quad (45)$$

Where:

$P_{SOC_{m_G,s,i,t}}$	=	SOC stock in the top 30 cm (or greater depth if required) of soil for management practice m_G, stratum *s*, sampling site *i* under project in year *t* (t C/ha)
$SOC_{m_G,s,i,t}$	=	SOC content in the top 30 cm of soil (or greater depth if required) for management practice m_G, stratum s, sampling site *i*, under project in year *t* (g C/kg soil)
$BD_{m_G,s,i,t}$	=	Soil bulk density in the top 30 cm of soil (or greater depth if required) for management practice m_G, stratum *s*, sampling site *i*, under project in year *t* (g soil/cm^3)
$Depth$	=	Top soil depth, for calculating grassland SOC stock in the top 30 cm of soil (or greater depth if required) (cm)
$FC_{m_G,s,i,t}$	=	Percentage of rocks larger than 2mm, roots, and other dead residues with a diameter in the top 30 cm of soil (or greater depth if required), for management practice m_G, stratum *s*, sampling site *i* under project in year *t* (percent)
0.1	=	Conversion factor for SOC to t C/ha
m_G	=	Index of management practice

[5] Stolbovoy et al., 2007

s	=	Index of stratum
i	=	Index of sampling site

Among the laboratory methods available to determination of TC and OC in soils, the total combustion method described in Nelson and Sommers (1996) is the most widely accepted and is therefore recommended for this purpose.

Calculate average carbon stock of all monitored sites in management practice m_G, stratum s, under project using the following:

$$P_{SOC_{m_G,s,t}} = \frac{\sum_{i=1}^{I} P_{SOC_{m_G,s,i,t}}}{I} \quad (46)$$

Where:

$P_{SOC_{m_G,s,t}}$	=	Average carbon stock in stratum *s* under project (t C/ha)
$P_{SOC_{m_G,s,i,t}}$	=	SOC stock in the top 30 cm (or greater depth if required) of soil for management practice m_G, stratum *s*, sampling site *i* under project in year *t* (t C/ha)
I	=	Monitored sites in stratum *s*, under project

The following is used to calculate the difference between the carbon stock for management practice m_G under project in year *t,* and the carbon stock under the baseline scenario, for all strata.

$$P_{m_G,t} = \sum_{s=1}^{S} (P_{SOC_{m_G,s,t}} - SOC_{s,Baseline}) \times PA_{m_G,s,t}) \quad (47)$$

Where:

$P_{m_G,t}$	=	Difference in the carbon stock between the project in year *t* and the baseline scenario (t C)
$PA_{m_G,s,t}$	=	Project areas with management practice m_G in stratum *s* in year *t* (ha)
$P_{SOC_{m_G,s,t}}$	=	Average carbon stock in stratum *s* under project in year *t* (t C / ha)
$SOC_{s,Baseline}$	=	Baseline SOC stock of stratum *s*, in the top 30 cm soil layer (or greater depth if required) (t C / ha)
S	=	Strata under project
s	=	Index of stratum

The following is applied to calculate average carbon stock of all management practice, under project in year *t*.

$$P_t = \sum_{m_G=1}^{M} P_{mG,t} \quad (48)$$

Where:

P_t	=	Carbon stock under project in year t (t C)
$P_{m_G,t}$	=	Difference in the carbon stock between the project in year *t* and the baseline scenario (t C)
M	=	Number of management practice

For the first monitoring of SOC stock, the annual project removals due to changes in SOC stock in year t must be calculated using the following:

.

$$PR_t = \frac{(P_t)}{n} \bullet \frac{44}{12} \quad (49)$$

Where:

PR_t	=	Project removals due to changes in SOC in year *t* (t CO_2e)
P_t	=	Carbon stock under project in year t (t C)
n	=	Number of years from the project start date to year t (years)

For the second and subsequent monitoring of SOC stock, the annual project removals due to changes in SOC stock in year t must be calculated using the following:

$$PR_t = \frac{(P_t - P_{t-f})}{f} \bullet \frac{44}{12} \quad (50)$$

Where:

PR_t	=	Project removals due to changes in SOC in year *t* (t CO_2e)
P_t	=	Carbon stock under project in year *t* (t C)
P_{t-f}	=	Carbon stock under project in year *t-f* (t C)
f	=	SOC monitoring frequency (years)

8.2.9 Uncertainty analysis

The methodology requires that all parameters used to estimate emissions and removals are conservative. Where conservative estimates are used that are based on verifiable literature sources or expert judgment, for the purposes of calculating uncertainty, it is not required to estimate a confidence interval for the parameter and uncertainty may be considered to be zero. Guidance on conservativeness of default parameters is given in the CDM EB *Guidelines on*

Conservative Choice and Application of Default Data in Estimation of the Net Anthropogenic GHG Removals by Sinks. Where parameter values are derived from sample surveys undertaken within the project area, and the sample size is large (ie, >30), a conservative estimate of baseline carbon sequestration by carbon pools or project emissions by GHG sources is given by adopting a value that represents the upper bound of the 95 percent confidence interval (ie, sample mean + 1.96 × standard error), while a conservative estimate of baseline emissions by GHG sources or carbon sequestration by carbon pools in the project scenario is given by adopting a value that represents the lower bound of the 95 percent confidence interval (ie, sample mean - 1.96 × standard error).[6]

Where Option 1 (use of a validated SOC model) is adopted to estimate changes in soil carbon stocks, quantification of uncertainty is required, and deductions for uncertainty must be applied following the procedures set out in this section. In addition to ex post deductions for uncertainty, the project proponent should also plan to diminish uncertainty in the process of planning data collection. The project proponent should refer to CDM EB approved *General Guidelines For Sampling And Surveys For Small-Scale CDM Project Activities* with a view to reducing uncertainty of model input parameters. The generation of model parameters follows the standard procedures on surveys and quality assurance in the collection and organization of data.

The project proponent must estimate the uncertainty of agricultural input parameters to the soil organic model selected. The project area should be stratified, and the sampling effort should represent the relevant strata in the sample frame. Where there is no specific survey guidance from national institutions, the project proponent must use a precision of 15 percent at the 95 percent confidence level as the criteria for reliability of sampling efforts. This reliability specification must be applied to determine the sampling requirements for assessing parameter values. The sampling intensity could be increased to ensure that the model parameters estimated from SGM lead to the achievement of a precision of ±15 at the 95 percent confidence level for the estimate of greenhouse gas emission reductions from the project. The project proponent should calculate the soil model response using the model input parameters with the upper and lower confidence levels. The range of model responses demonstrates the uncertainty of the soil modeling.

Step 1: Calculate the values for all input parameters at the upper and lower confidence limit.

Calculate the mean, X_p and standard deviation, ∂_p for all parameters measured in SGM, then the standard error in the mean is given by:

[6] This approach assumes a large sample size and a normal distribution. Where sample size is small, and/or where the assumption of a normal distribution is not appropriate, alternative methods to derive a conservative estimate may be adopted following the guidance provided in the *2006 IPCC Guidelines for National Greenhouse Gas Inventories,* Vol. 1, Chapter 3.

$$SE_p = \frac{\partial_p}{\sqrt{n_p}} \quad (51)$$

Where:

SE_p	=	Standard error in the mean of parameter, *p* in year *t*
∂_p	=	Standard deviation of the parameter p in year *t*
n_p	=	Number of samples used to calculate the mean and standard deviation of parameter *p*

Assuming that values of the parameter are normally distributed about the mean, the minimum and maximum values for the parameters are given in the following:

$$P_{\min} = \overline{X_p} - 1.96 * SE_p$$
$$P_{\max} = \overline{X}_p + 1.96 * SE_p \quad (52)$$

Where:

$P_{\min}$	=	Minimum value of the parameter at the 95 percent confidence interval
$P_{\max}$	=	Maximum value of the parameter at the 95 percent confidence interval
SE_p	=	Standard error in the mean of parameter, *p* in year *t*
1.96	=	Value of the cumulative normal distribution at 95 percent confidence interval

Step 2: Calculate the project removals due to changes in soil organic carbon with the minimum and maximum values of the input parameters

The project removals due to changes in soil organic carbon using the minimum and maximum values of the parameters is given bin the following:

$$PR_{\min,t} = Model(P_{\min}, Temperature_{\max}, \Pr ecipitation_{\max}, ClayContent_{\min})$$
$$PR_{\max,t} = Model(P_{\max}, Temperature_{\min}, \Pr ecipitation_{\min}, ClayContent_{\max}) \quad (53)$$

Where:

$PR_{\min,t}$	=	Minimum value of project removals due to changes in soil organic carbon at the 95 percent confidence interval in year *t*
$PR_{\max,t}$	=	Maximum value of project removals due to changes in soil organic carbon at the 95 percent confidence interval in year *t*

Step 3: Calculate the uncertainty in the model output

The uncertainty in the output model must be calculated as described in the following:

$$UNC_t = \frac{\left|PR_{\max,t} - PR_{\min,t}\right|}{2 * PR_t} \quad (54)$$

Step 4: Adjust the estimate of soil sequestration based on the uncertainty in the model output

If the uncertainty of soil models is less than or equal to 15 percent of the mean value then the project proponent may use the estimated value without any deduction for conservativeness or increase in sampling.

If the uncertainty of soil models is greater than 15 percent but less than or equal to 30 percent of the mean value, then the project proponent may use the estimated value subject to a deduction calculated as described in the following:

$$PR_{Deduction,t} = PR_t * (UNC_t - 15\%) \quad (55)$$

And the following term will be used for calculation of net GHG emission reductions in Equation 60 in place of PR_t:

$$PR_{Adj,t} = PR_t - PR_{Deduction,t} \quad (56)$$

Where:

PR_t	=	Estimate of project removals due to changes in soil organic carbon in year *t* (t CO_2e)
PR_{Unc}	=	Estimate of uncertainty in the mean of changes in soil organic carbon in year *t* (t CO_2e)
$PR_{Deduction,t}$	=	Calculated deduction to the estimate of the change in soil organic removals year *t* (t CO_2e)
$PR_{Adj,t}$	=	Adjusted estimate of project removals due to changes in soil organic carbon in year *t* (t CO_2e)

In this way, when the uncertainty is 15 percent or less than 15 percent there is no deduction and when the uncertainty is between 15 and 30 percent a deduction as calculated in Step 4 above will apply.

If the uncertainty of soil models is greater than 30 percent of the mean value then the project proponent should increase the sample size of the input parameters until the soil model uncertainty is better than ± 30 percent.

8.2.10 Project net GHG emissions by sources and removals by sinks

The net GHG emissions and removals by sinks in project year *t* are given by:

$$PE_t = PE_{N_2O_{SN},t} + PE_{N_2O_{NF},t} + PE_{GHG_{BB},t} + PE_{CH_{4EF},t} + PE_{GHG_{MD},t} + PE_{FC,t} - PRWP_t - PR_t \quad (57)$$

Where:

PE_t	=	Project net GHG emissions by sources and removals by sinks in year *t* (t CO_2e)
$PE_{N_2O_{SN},t}$	=	Project N_2O emissions due to fertilizer use in year t (t CO_2e)
$PE_{N_2O_{NF},t}$	=	Project N_2O emissions as a result of N-fixing species within the project area in year *t* (t CO_2e)
$PE_{GHG_{BB,t}}$	=	Project GHG emissions from biomass burning in year *t* (t CO_2e)
$PE_{CH_{4EF},t}$	=	Project CH_4 emissions from enteric fermentation in year *t* (t CO_2e)
$PE_{GHG_{MD},t}$	=	Project GHG emissions from manure management in year *t* (t CO_2e)
$PE_{FC,t}$	=	Project CO_2 emissions from farming machine fossil fuel consumption in year *t* (t CO_2)
$PRWP_t$	=	Project average net change in carbon stocks of existing woody biomass in year *t* (t CO_2)
PR_t	=	Project removals due to changes in SOC in year *t* (t CO_2e)

8.3 Leakage Emissions

Under this methodology, project activities must not involve increase in use of fossil fuels or fuel wood and must not include significanlty different manure management practices. Therefore the only potential sources of leakage in this methodology are the following:

1) Market leakage due to reduction in the production of livestock products within the project boundary;
2) Displacement of grazing beyond the project boundary.

Market leakage must be assessed and quantified using VCS Module *VMD0033 Estimation of Emissions from Market Leakage*. The result of applying the module is estimation of the parameter $LE_{M,t}$. Leakage from displacement of grazing activities to outside the project boundary must be assessed and quantified using VCS module *VMD0040 Leakage from Displacement of Grazing Activities*. The result of applying that module is estimation of the parameter $LE_{GD,t}$. Leakage emissions must be calculated as:

$$LE_t = LE_{M,t} + LE_{GD,t} \quad (58)$$

Where:

LE_t	=	Leakage emissions in year *t* (t CO_2e)
$LE_{M,t}$	=	Leakage emissions due to market leakage in year *t* (t CO_2e)
$LE_{GD,t}$	=	Leakage emissions due to grazing displacement in year *t* (t CO_2e)

8.4 Summary of GHG Emission Reduction and/or Removals

The amount of emission reductions achieved by the project in project year *t* must be calculated using the following Equation 59. Where relevant, emission reductions must be adjusted for uncertainty, as described in Section 8.2.9.

$$ER_t = BE_b - PE_t - LE_t \tag{59}$$

Where:

ER_t	=	Emission reductions in year *t* (t CO_2e)
BE_b	=	Baseline emissions and removals in year *b* (t CO_2e)
PE_t	=	Project emissions and removals in year *t* (t CO_2e)
LE_t	=	Leakage emissions in year *t* (t CO_2e)

The amount of emission reductions that can be issued as credits during the monitoring period must be calculated using the Eqauation 60. The emissions reductions generated during the monitoring period should be summed from the first year of the monitoring period, t_f, to the final year of the monitoring period, t_m.

AFOLU buffer credits must be deposited into the AFOLU pooled buffer account when the project requests issuance of VCUs, in accordance with the procedures in the VCS document *Registration and Issuance Process*. AFOLU buffer credits must be deducted from the total emission reducitons achieved to determine the total number of emission reductions elibile to be issued as VCUs, as calculated in the following:

$$VCU_t = ER_t - BC_t \tag{60}$$

Where:

VCU_t	=	Emission reductions eligible to be issued as VCUs in year *t* (t CO_2e)
ER_t	=	Emission reductions in year *t* (t CO_2e)
BC_{tm}	=	AFOLU buffer credits in year *tm* (t CO_2e)

The amount of AFOLU buffer credits that must be depositied into the AFOLU pooled buffer account must be calculated by multiplying the non-permanence risk rating by the change in carbon stocks in a given monitoring period. The non-permanence risk rating must be determined using the VCS *AFOLU Non-Permanence Risk Tool*. The amount of AFOLU buffer credits required for the monitoring period can be determined for the first monitoring period using Equation 61 or subsequent monitoring periods using Equation 62.

$$BC_t = RR_t * (PRWP_t + PR_t - BRWP_b) \tag{61}$$

or

$$BC_t = RR_t * (PRWP_t + PR_t - PRWP_{tp} - PR_{tp}) \quad (62)$$

Where:

BC_{tm}	=	AFOLU buffer credits in year *tm* (t CO_2e)
RR_t	=	Non-permanence risk rating in year *t* (percent)
$PRWP_t$	=	Project average net change in carbon stocks of existing woody biomass for species *j*, in year *t* (t CO_2)
PR_t	=	Project removals due to changes in SOC in year *t* (t CO_2e)
$BWRP_b$	=	Baseline removals from existing woody perennials in baseline year *b* (t CO_2)
$PRWP_{tp}$	=	Project average net change in carbon stocks of existing woody biomass at the end of the previous monitoring period *tp* (t CO_2)
PR_{tp}	=	Project removals due to changes in SOC at the end of the previous monitoring period *tp* (t CO_2e)

9 MONITORING

The purpose of the monitoring plan is to define a series of monitoring tasks to be conducted in order to ensure that the GHG emissions reductions claimed by the proposed project are real, additional and measurable. Subject to the specific requirements and guidance below, procedures specified in monitoring plans should meet the requirements of the most recent version of the *VCS Standard* and other VCS rules, and be consistent with guidance in internationally accepted guidance documents such as Volume 4 (Agriculture, Forestry and Other Land Use (AFOLU)) of the *2006 IPCC Guidelines on National Greenhouse Gas Inventories*.

Where sampling is conducted, procedures must attain a precision of 15 percent at the 95 percent confidence level.

Monitoring plans must include procedures for managing data quality that are consistent with internationally accepted guidance documents such as IPCC (2003) Chapter 5, or IPCC (2000) Chapter 8.

9.1 Data and Parameters Available at Validation

Data/Parameter	GWP_{N_2O}
Data unit	t CO_2e/t N_2O
Description	Global-warming potential for N_2O
Equations	1, 7, 10, 21, 26, 30 and 33

Source of data	GWP_{N_2O} must be obtained from the IPCC Second Assessment Report
Value applied	310
Justification of the choice of data or description of measurement methods and procedures applied	
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comments	

Data / Parameter	EF_{Nfert}
Data unit	kg N_2O-N/kg N applied
Description	N_2O emission factor for synthetic N fertilizer use
Equations	2 and 23
Source of data	Peer-reviewed scientific studies or default values from *IPCC Guidelines for National Greenhouse Gas Inventories*
Value applied	Project-specific value or IPCC default value
Justification of the choice of data or description of measurement methods and procedures applied	Where detailed emission factors from peer-reviewed scientific studies, specific to the project area or country, taking into account specific environmental, climatic and soil management conditions, are available, such data must be applied. Where detailed emission factors are unavailable, the default Tier 1 N_2O emission factor recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (Table 11.1, Chapter 11, Volume 4) or the most recent version of IPCC good practice guidance for AFOLU, must be followedAFOLU, must be followed.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comments	

Data Unit / Parameter	EF_{Nfix}
Data unit	kg N_2O-N/kg N input
Description	N_2O emission factor for N from N-fixing species

Equations	26
Source of data	Peer-reviewed scientific studies or default values from I*PCC Guidelines for National Greenhouse Gas Inventorie*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where detailed emission factors from peer-reviewed scientific studies, specific to the project area or country, taking into account specific environmental, climatic and soil management conditions, are available, such data must be applied. Where detailed emission factors are unavailable, the default Tier 1 N2O emission factor recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (Table 11.1, Chapter 11, Volume 4) or the most recent version of IPCC good practice guidance for AFOLU, must be followed.
Purpose of data	Calculation of project emissions
Comment	

Data Unit / Parameter	EF_{Nfix}
Data unit	kg N_2O-N/kg N input
Description	N_2O emission factor for N from N-fixing species
Equations	26
Source of data	Peer-reviewed scientific studies or default values from I*PCC Guidelines for National Greenhouse Gas Inventorie*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where detailed emission factors from peer-reviewed scientific studies, specific to the project area or country, taking into account specific environmental, climatic and soil management conditions, are available, such data must be applied. Where detailed emission factors are unavailable, the default Tier 1 N2O emission factor recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (Table 11.1, Chapter 11, Volume 4) or the most recent version of IPCC good practice guidance for AFOLU, must be followed.
Purpose of data	Calculation of project emissions

Data Unit / Parameter	$M_{SNi,b}$
Data unit	t fertilizer
Description	Mass of synthetic N fertilizer type i applied in baseline year *b*

Equations	3
Source of data	Documented management records or sample surveys
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	The mass of synthetic N fertilizer must be based on documented management records of all synthetic N fertilizer types applied during the baseline period. Documented management records may include fertilizer application records or fertilizer purchase records. For new management entities or where such records are unavailable, a conservative estimate of the mass of synthetic N fertilizer applied per ha must be provided based on a sample survey conducted in the project area provide a conservative estimate of baseline N fertilizer application over the baseline period. Where data from sample surveys are used, a conservative estimate must be made following the guidance in Section 8.2.9. The total mass of synthetic N fertilizer applied must be estimated by multiplying the mass of synthetic N fertilizer applied per ha by the total grassland area involved in the project.
Purpose of data	Calculation of baseline emissions
Comment	

Data Unit / Parameter	$NC_{SNi,b}$
Data unit	g N/g fertilizer
Description	Nitrogen content of synthetic N fertilizer type i applied in baseline year *b*
Equations	3
Source of data	Manufacturer product label or other manufacturer data
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	The nitrogen content must be recorded for each synthetic N fertilizer type i that has been applied in the baseline scenario. The value must be obtained from the product description stated by the manufacturer on the product label.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	$Frac_{GAS,F}$

Data unit	kg N volatilized/kg N applied
Description	Fraction of synthetic N fertilizer that volatilizes as NH_3 and NO_x
Equations	3, 4, 24 and 25
Source of data	Peer reviewed scientific studies or default values from *IPCC Guidelines for National Greenhouse Gas Inventories*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where detailed data from peer-reviewed scientific studies, specific to the project area or country are available, such data must be applied. Where detailed data are unavailable, the default value recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (Table 11.3, Chapter 11, Volume 4) or the most recent version of IPCC good practice guidance for AFOLU, must be followed.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	$EF_{4,SN}$
Data unit	kg N2O-N/(kg NH_3-N + NOx-N volatilized)
Description	N_2O emission factor for atmospheric deposition of synthetic N on soils and water surfaces
Equations	4 and 25
Source of data	Peer reviewed scientific studies or default values from *IPCC Guidelines for National Greenhouse Gas Inventories*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where detailed data from peer-reviewed scientific studies, specific to the project area or country are available, such data must be applied. Where detailed data are unavailable, the default value recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (Table 11.3, Chapter 11, Volume 4) or the most recent version of IPCC good practice guidance for AFOLU, must be followed.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	$EF_{4,MD}$
Data unit	kg N_2O-N/(kg NH_3-N + NOx-N volatilized)
Description	N_2O emission factor for atmospheric deposition of urine and manure N on soils and water surfaces
Equations	14 and 37
Source of data	Peer reviewed scientific studies or default values from *IPCC Guidelines for National Greenhouse Gas Inventories*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where detailed data from peer-reviewed scientific studies, specific to the project area or country are available, such data must be applied. Where detailed data are unavailable, the default value recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (Table 11.3, Chapter 11, Volume 4) or the most recent version of IPCC good practice guidance for AFOLU, must be followed.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	$A_{B,b}$
Data unit	Ha
Description	Area burned in baseline year *b*
Equations	6 and 7
Source of data	Documented management records or sample surveys
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Area burned in each year during the baseline period must be based on documented fire management records averaged over the five year period prior to the project start date. For new management entities or where such records are unavailable, a conservative estimate of the area burned during the baseline period must be provided based on a sample survey conducted in the project area. The sample survey must provide a conservative estimate of the area burned in each year during the baseline period. Where sample survey data are used, a conservative estimate of the area burned must be made following the guidance in Section 8.2.9. The annual area burned must be equal to the percentage area burned times the total grassland area involved in the

	project.
Purpose of data	Calculation of baseline emissions
Comment	

Data Unit / Parameter	$M_{B,b}$
Data unit	t biomass dm/ha
Description	Aboveground biomass in terms of dry matter burned in baseline year *b*
Equations	6 and 7
Source of data	Documented management records or sample surveys
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Aboveground biomass burned under baseline must be based on documented fire management records averaged over the baseline period. For new management entities or where such records are unavailable, aboveground biomass burned under the baseline scenario must be conservatively estimated based on sample surveys conducted before the project start date. Where sample survey data are used, the mean aboveground biomass burned under the baseline scenario must be converted to a conservative estimate following the guidance on conservative parameter estimates presented in Section 8.2.9.
Purpose of data	Calculation of baseline emissions

Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	GWP_{CH_4}
Data unit	t CO_2e/t CH_4
Description	Global-warming potential for CH_4
Equations	6, 8, 15, 29 and 31
Source of data	GWP_{CH_4} must be obtained from the IPCC Second Assessment Report
Value applied	21
Justification of choice of data or description of measurement methods and procedures applied	
Purpose of data	Calculation of baseline emissions

	Calculation of project emissions
Comment	

Data Unit / Parameter	$P_{l,b}$
Data unit	Head
Description	Population of grazing livestock type l, in baseline year *b*
Equations	8, 13 and 15
Source of data	Documented management records or sample surveys
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Population of grazing livestock must be based on documented management records, averaged over the baseline period. For new management entities or where such records are unavailable, a conservative estimate of the animal population must be provided based on a sample survey of the animal population grazing in the project area year prior to the project start dateduring the baseline period. The design of the sample survey must consider the annual livestock population during the baseline period, which may not be the same as the population present at the time of the survey. Where data from sample surveys are used, a conservative estimate of the baseline livestock population must be made following the guidance on using conservative parameter estimates derived from sample surveys, presented in Section 8.2.9.
Purpose of data	Calculation of baseline emissions
Comment	

Data Unit / Parameter	EF_l
Data unit	kg CH_4/(head * year)
Description	Enteric CH_4 emission factor per head of livestock type l per year
Equations	8 and 31
Source of data	Peer reviewed scientific studies or default values from *IPCC Guidelines for National Greenhouse Gas Inventories*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where detailed data from peer-reviewed scientific studies, specific to the project area or country are available, such data must be applied. Where detailed data are unavailable, the default value

	recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (Table 10.10 or 10.11, Chapter 10, Volume 4) or the most recent version of IPCC good practice guidance for AFOLU, must be followed. When data from IPCC sources are used, the project proponentmust refer to the tables in Annex 10A.1 of the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* to ensure that the value selected reflects the underlying animal characteristics appropriate to the selected value.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	$EF_{3,PRP,CPP}$
Data unit	kg N_2O-N/kg N input
Description	N_2O emission factor for cattle (dairy, non-dairy and buffalo), poultry and pigs manure and urine deposited on of applied to grassland
Equations	11 and 34
Source of data	Peer reviewed scientific studies or default values from *IPCC Guidelines for National Greenhouse Gas Inventories*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where detailed data from peer-reviewed scientific studies, specific to the project area or country are available, such data must be applied. Where detailed data are unavailable, the default value recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (Table 10.10 or 10.11, Chapter 10, Volume 4) or the most recent version of IPCC good practice guidance for AFOLU, must be followed. When data from IPCC sources are used, the project proponent must refer to the tables in Annex 10A.1 of the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* to ensure that the value selected reflects the underlying animal characteristics appropriate to the selected value.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	$EF_{3,PRP,SO}$
Data unit	kg N_2O-N/kg N input
Description	N_2O emission factor for sheep and other animals manure and urine deposited on of applied to grassland
Equations	12 and 35
Source of data	Peer reviewed scientific studies or default values from *IPCC Guidelines for National Greenhouse Gas Inventories*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where detailed data from peer-reviewed scientific studies, specific to the project area or country are available, such data must be applied. Where detailed data are unavailable, the default value recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (Table 10.10 or 10.11, Chapter 10, Volume 4) or the most recent version of IPCC good practice guidance for AFOLU, must be followed. When data from IPCC sources are used, the project proponentmust refer to the tables in Annex 10A.1 of the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* to ensure that the value selected reflects the underlying animal characteristics appropriate to the selected value.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	Nex_l
Data unit	kg N deposited/(t livestock mass * day)
Description	Nitrogen excretion of livestock type *l*
Equations	13 and 36
Source of data	Peer reviewed scientific studies or default values from *IPCC Guidelines for National Greenhouse Gas Inventories*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where detailed data from peer-reviewed scientific studies, specific to the project area or country are available, such data must be applied. Where detailed data are unavailable, the default value recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (Table 10.10 or 10.11, Chapter 10, Volume 4) or the most recent version of IPCC good practice

	guidance for AFOLU, must be followed. When data from IPCC sources are used, the project proponentmust refer to the tables in Annex 10A.1 of the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* to ensure that the value selected reflects the underlying animal characteristics appropriate to the selected value.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	$W_{l,b}$
Data unit	Kg
Description	Average weight of livestock *l*, in baseline year *b*
Equations	
Source of data	Peer reviewed scientific literature or expert judgment.
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Data from the peer-reviewed scientific literature or expert judgement that are specific to the project area.
Purpose of data	Calculation of baseline emissions
Comment	

Data Unit / Parameter	$W_{l,p}$
Data unit	Kg
Description	Average weight of livestock under project
Equations	
Source of data	Peer reviewed scientific literature or expert judgment.
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Data from the peer-reviewed scientific literature or expert judgment that are specific to the project area. To ensure that the estimated N2O emission reductions from manure and urine deposited on grassland soil are conservative, the value selected for the average weight of livestock l under project ($W_{l,p}$) must be greater than the average weight of livestock l, in baseline year b ($W_{l,p}$). Moreover, the project proponent must justify why the values selected for these parameters results in emission reductions that are conservative.

Purpose of data	Calculation of project emissions
Comment	

Data Unit / Parameter	$Days_{l,b}$
Data unit	Days
Description	Grazing days for livestock type *l* in baseline year *b*
Equations	8, 13 and 15
Source of data	Documented management records or sample surveys
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Grazing days inside the project area in the baseline must be based on documented management records, averaged over the baseline period. For new management entities or where such records are unavailable, grazing days must be based on the average annual grazing days from a sample survey of livestock grazing in the project area in the year prior to the project start date. Where data from sample surveys are used, a conservative estimate must be made to enable conservative estimates of livestock enteric fermentation and manure management emissions.
Purpose of data	Calculation of baseline emissions
Comment	

Data Unit / Parameter	$H_{l,b}$
Data unit	Hours
Description	Average grazing hours for livestock type *l* per day during the grazing season in baseline year *b*
Equations	13 and 15
Source of data	Documented management records or sample surveys
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	The average grazing hours per day in the baseline must be based on documented management records, averaged over the baseline period. For new management entities or where such records are unavailable, a conservative estimate of average grazing hours must be provided based on the average grazing hours in each grazing season taken from a sample survey of livestock grazing

	in the project area in the year prior to the project start date. Where data from sample surveys are used, a conservative estimate must be made to enable a conservative estimate of livestock manure management emissions.
Purpose of data	Calculation of baseline emissions
Comment	

Data Unit / Parameter	$Frac_{GAS,MD}$
Data unit	kg N volatilized/kg of N deposited
Description	Fraction of volatilization from manure and urine deposited by grazing animals as NH_3 and NO_x
Equations	13, 14, 36 and 37
Source of data	Peer reviewed scientific studies or default values from I*PCC Guidelines for National Greenhouse Gas Inventoriespeer-reviewed*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where detailed data from peer-reviewed scientific studies, specific to the project area or country are available, such data must be applied. Where detailed data are unavailable, the default value recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (Table 10.10 or 10.11, Chapter 10, Volume 4) or the most recent version of IPCC good practice guidance for AFOLU, must be followed.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	EF_{lM}
Data unit	kg CH_4/(head * year)
Description	CH_4 emission factor from manure of livestock type *l*
Equations	15 and 38

Source of data	Peer reviewed scientific studies or default values from *IPCC Guidelines for National Greenhouse Gas Inventories*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where detailed data from peer-reviewed scientific studies, specific to the project area or country are available, such data must be applied. Where detailed data are unavailable, the default value recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (Table 10.10 or 10.11, Chapter 10, Volume 4) or the most recent version of IPCC good practice guidance for AFOLU, must be followed.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	$FC_{p,j,k,B}$
Data unit	kg fuel/year
Description	Fuel consumption by type *k*, machine type *j*, parcel grassland *p*, in baseline
Equations	16
Source of data	Peer reviewed scientific studies or default values from *IPCC Guidelines for National Greenhouse Gas Inventories*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Documented management records or sample surveys. Fuel consumption for grassland management under the baseline scenario must be estimated on the basis of management records , such as fuel consumption logs, averaged over the baseline period. For new management entities or where such records are unavailable, a conservative estimate of fuel consumption must be provided based on a sample survey conducted in the project area regarding fuel consumption during the baseline period. Where data from sample surveys are used, a conservative estimate must be made following the guidance in Section 8.2.9. A sample survey mean may be converted to a conservative estimate by subtracting 1.96 × the standard error from the mean.
Purpose of data	Calculation of baseline emissions
Comment	

Data Unit / Parameter	$EF_{CO_2,k}$
Data unit	t CO_2/GJ
Description	CO_2 emission factor by fuel type *k*
Equations	16 and 39
Source of data	Peer reviewed scientific studies or default values from *IPCC Guidelines for National Greenhouse Gas Inventories*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where detailed emissions factors from peer-reviewed scientific studies, specific to the country are available, such data must be applied. Where detailed data are unavailable, the default value recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* or the most recent version of IPCC good practice guidance for AFOLU, must be followed.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	NCV_k
Data unit	GJ/t fuel
Description	Thermal value of fuel type *k*
Equations	16 and 39
Source of data	Peer reviewed scientific studies or default values from *IPCC Guidelines for National Greenhouse Gas Inventories*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where detailed emissions factors from peer-reviewed scientific studies, specific to the country are available, such data must be applied. Where detailed data are unavailable, the default value recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* or the most recent version of IPCC good practice guidance for AFOLU, must be followed.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	$A_{B,j,s}$
Data unit	Ha
Description	Area of trees and shrubs under baseline, for species j in stratum *s*
Equations	18
Source of data	Documented management records or sample surveys
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Area of trees and shrubs under the baseline scenario must be obtained from a field survey before the project start date.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	CF_j
Data unit	t C/t dm
Description	Carbon fraction for species *j*
Equations	18 and 41
Source of data	Default values in the CDM A/R Methodological Tool for *Estimation of carbon stocks and change in carbon stocks of trees and shrubs in A/R CDM project activities*
Value applied	0.50 for tree species; 0.49 for shrub species.
Justification of choice of data or description of measurement methods and procedures applied	
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	R_j
Data unit	t dm belowground biomass/t dm aboveground biomass
Description	Root to shoot ratio of species *j*
Equations	19 and 42

Source of data	Default values in the CDM A/R Methodological Tool for *Estimation of carbon stocks and change in carbon stocks of trees and shrubs in A/R CDM project activities.*
Value applied	0.26 for tree species; 0.4 for shrub species
Justification of choice of data or description of measurement methods and procedures applied	
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	$G_{AB,B,j,s}$
Data unit	t dm/ha
Description	Average annual increase in existing aboveground woody biomass of species *j* in stratum *s*, under baseline.
Equations	19
Source of data	Use one of the methods for the estimation of carbon stocks and change in carbon stocks in trees and shrubs in the baseline outlined in the latest version of the CDM tool for *Estimation of carbon stocks and change in carbon stocks of trees and shrubs in A/R CDM project activities*. Follow the measurement, sampling, modeling and default estimation procedures specified in this tool.
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	
Purpose of data	Calculation of baseline emissions
Comment	

Data Unit / Parameter	$SOC_{s,Baseline}$
Data unit	t C/ha
Description	Baseline SOC stock in the top 30 cm of soil layer (or greater depth if required) in stratum *s*
Equations	43

Source of data	Results from biogeochemical model or project measurements
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where Option 1, outlined in Section 8.2.8, is applied to estimate project removals due to changes in SOC, the project proponent must use the biogeochemical model selected under Option 1 to conservatively determine $SOC_{s,Baseline}$, by setting the value of this parameter to the computed maximum carbon stocks that occurred in the designated project area and stratum within the previous 10 years. Where Option 2 is applied to estimate project removals due to changes in SOC, the project proponent must follow the procedures for the sampling and measurement of soil properties, including bulk density and organic carbon concentrations, that are outlined in Option 2 in Section 8.2.8to determine the value of $SOC_{s,Baseline}$, less than two years prior to the project start time. The General Guidelines for Sampling and Surveys for Small-Scale CDM Project Activities should be followed to determine the sampling procedures and the sample size.
Purpose of data	Calculation of project emissions
Comment	

Data Unit / Parameter	$SOC_{m_G,s,Equil}$
Data unit	t C/ha
Description	SOC stocks, in the top 30 cm of soil layer (or greater depth if required), at equilibrium for grassland with management practice of m_G in stratum *s*.
Equations	43
Source of data	Results from biogeochemical model
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	SOC stocks at equilibrium for each management practice and stratum must be obtained from the results of the biogeochemical model.
Purpose of data	Calculation of project emissions
Comment	

Data Unit / Parameter	EF_{N_2O}
Data unit	g N_2O/kg dry matter burnt
Description	N_2O emission factor for biomass burning
Equations	7 and 30
Source of data	Peer reviewed scientific studies or default values from *IPCC Guidelines for National Greenhouse Gas Inventories*
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where detailed data from peer-reviewed scientific studies, specific to the project area or country are available, such data must be applied. Where detailed data are unavailable, the default value recommended by the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* (Table 2.5, Chapter 2, Volume 4) or the most recent version of IPCC good practice guidance for AFOLU, must be followed.peer-reviewed.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

Data Unit / Parameter	$D_{m_G,s}$
Data unit	Year
Description	The transition period required for SOC to be at equilibrium after a change in management practice of m_G in stratum *s*.
Equations	43
Source of data	Peer reviewed scientific studies
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	The transition period required for SOC to be at equilibrium after a change in management practice must be obtained from literature, local or regional studies or the modeling exercise. Where detailed data are unavailable, the project must apply a transition period of 20 years.
Purpose of data	Calculation of project emissions
Comment	

Data Unit / Parameter	f

Data unit	Year
Description	SOC monitoring frequency
Equations	50
Source of data	Project records
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Where the project applies option 2 to directly measure SOC, the frequency of SOC measurements must be at least once every five years.
Purpose of data	Calculation of project emissions
Comment	

9.2 Data and Parameters Monitored

Data Unit / Parameter	$M_{SNi,t}$
Data unit	t fertilizer
Description	Mass of synthetic N fertilizer type *i* applied in year *t*
Equations	24
Source of data	Project records
Description of measurement methods and procedures to be applied	The mass must be recorded just after the application of synthetic N fertilizer for each fertilizer type applied for each year.
Frequency of monitoring/recording	Each application of fertilizer during year t
QA/QC procedures to be applied	Guidelines provided in IPCC, 2003 Chapter 5 or IPCC, 2000 Chapter 8
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$NC_{SNi,p}$
Data unit	g N/g fertilizer
Description	Nitrogen content of synthetic N fertilizer type *i* applied under project
Equations	24
Source of data	Manufacturer product label or other manufacturer data

Description of measurement methods and procedures to be applied	The nitrogen content must be recorded for each synthetic N fertilizer type *i* that has been applied in the baseline scenario or project. The value must be obtained from the product description stated by the manufacturer on the product label.
Frequency of monitoring/recording	Each application during project crediting period in year t
QA/QC procedures to be applied	Guidance provided in IPCC, 2003 chapter 5 or IPCC, 2000 chapter 8 must be applied
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$Area_{g,t}$
Data unit	ha
Description	Annual area of N-fixing species *g* in year t
Equations	27
Source of data	Project records
Description of measurement methods and procedures to be applied	Record the area of N-fixing species by all households involved in the project.
Frequency of monitoring/recording	Annually, at the beginning of growing season.
QA/QC procedures to be applied	Where the difference between the recorded and the new reading is more than 10 percent, reasons for the difference must be discussed with the staff responsible for taking both measurements, and if necessary the $Area_{g,p,t}$ should be re-measured.
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$Crop_{g,t}$
Data unit	t dm/ha
Description	Annual dry matter, including aboveground and below ground, returned to grassland soils for N-fixing species *g* in year t.
Equations	27
Source of data	Project records
Description of measurement	Measure annual dry matter, including aboveground and below

methods and procedures to be applied	ground, returned to grassland soils for N-fixing species g in year t. The sample size of household number must ensure precision at 95±15 precision.
Frequency of monitoring/recording	Annually, at the end of growing season.
QA/QC procedures to be applied	The sample collection should be carried out by experts or well-trained staff. Where the difference between the recorded and the new reading is more than 10 percent, reasons for the difference must be discussed with the staff responsible for taking both measurements, and if necessary the $Crop_{g,t}$ should be re-measured.
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$N_{content,g}$
Data unit	t N/t dmt N
Description	Fraction of N in dry matter for N-fixing species g under project
Equations	27
Source of data	Project records
Description of measurement methods and procedures to be applied	Where detailed data from peer-reviewed scientific studies, specific to the project area or country are available, such data must be applied. Where detailed data are unavailable, an peer-reviewedexpert survey within the project area must be performed before the start of the project. Data must be surveyed by collecting biomass (aboveground and below ground) from at least three plots (1m*1m) of each N-fixing species in each sampled household. Send the samples to a qualified laboratory to analyze the N content in the biomass.
Frequency of monitoring/recording	Annually
QA/QC procedures to be applied	A sufficient number of plots for sampling $N_{content,\mathrm{p},g}$ must be used to ensure that a precision of 15 percent at the 95 percent confidence level is attained. Guidance provided in IPCC, 2003 chapter 5 or IPCC, 2000 chapter 8 must be applied must be applied for guidance on sampling methods and QA/QC procedures. The sample collection must be carried out by appropriately trained staff. The measurement of the N content in the biomass must be carried out by a laboratory that can

	demonstrate adherence to the principles of good laboratory practices, outlined in OECD (1998).
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$A_{B,t}$
Data unit	Ha
Description	Area burnt in year t during the project crediting period
Equations	29 and 30
Source of data	Project records
Description of measurement methods and procedures to be applied	Measure and record the area burnt after the fire occurrence
Frequency of monitoring/recording	Each burning activity in year t during project crediting period
QA/QC procedures to be applied	Where the difference between the recorded burnt area and the new reading is more than 10 percent, reasons for the difference must be discussed with the staff responsible for taking both measurements, and if necessary the burnt area should be re-measured.
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$M_{B,t}$
Data unit	t biomass/ha
Description	Aboveground biomass burnt, excluding litter and dead wood under project in year t.
Equations	29 and 30
Source of data	Project records
Description of measurement methods and procedures to be applied	Measure the aboveground biomass of grassland before and after the fire management for at least three plots (1m*1m). The difference of the aboveground biomass is the aboveground biomass burnt.
Frequency of monitoring/recording	Each burning activity in year t during the project crediting period
QA/QC procedures to be	A sufficient number of plots for sampling $M_{B,p,t}$ must be used

applied	to ensure that a precision of 15 percent at the 95 percent confidence level is attained. Guidance provided in IPCC, 2003 chapter 5 or IPCC, 2000 chapter 8 must be applied must be used for guidance on sampling methods and QA/QC procedures.
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$P_{l,t}$
Data unit	*head*
Description	Population of livestock type *l* under project in year t
Equations	31, 36 and 38
Source of data	Project records
Description of measurement methods and procedures to be applied	Record numbers of grazing livestock by type. The sample size of household number must ensure that a precision of 15 percent at the 95 percent confidence level is attained. The value must be based on the grazing numbers; annual or seasonal average population of grazing livestock by type.
Frequency of monitoring/recording	Annually
QA/QC procedures to be applied	Guidance provided in IPCC, 2003 chapter 5 or IPCC, 2000 chapter 8 must be applied
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$H_{l,t}$
Data unit	Hours
Description	Average grazing hours per day of livestock type *l* during grazing season in year t
Equations	36 and 38
Source of data	Project records
Description of measurement methods and procedures to be applied	Record the average number of grazing hours per day during grazing season in year t. The sample size of household number must ensure that a precision of 15 percent at the 95 percent confidence level is attained.
Frequency of	Annually

monitoring/recording	
QA/QC procedures to be applied	Guidance provided in IPCC, 2003 chapter 5 or IPCC, 2000 chapter 8 must be applied
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$Days_{l,t}$
Data unit	Days
Description	Grazing days of livestock *l* in year t under project
Equations	31, 36 and 38
Source of data	Project records
Description of measurement methods and procedures to be applied	Record the grazing days in year t. The sample size of household number must ensure that a precision of 15 percent at the 95 percent confidence level is attained.
Frequency of monitoring/recording	At the end of every grazing season in year t
QA/QC procedures to be applied	Guidance provided in IPCC, 2003 chapter 5 or IPCC, 2000 chapter 8 must be applied
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$G_{AB,j,s,t}$
Data unit	t dm/ha
Description	Average increase in existing aboveground woody biomass of species *j*, in stratum *s*, under project for year *t*.
Equations	42
Source of data	Project records
Description of measurement methods and procedures to be applied	Use one of the methods for estimating changes in carbon stock of trees and shrubs between two points in time for project activities outlined in the latest version of the CDM tool for *Estimation of carbon stocks and change in carbon stocks of trees and shrubs in A/R CDM project activities*. Follow the sampling, measurement, modeling, and monitoring procedures specified in this tool.
Frequency of monitoring/recording	At the end of every monitoring period

QA/QC procedures to be applied	Quality control/quality assurance (QA/QC) procedures prescribed under national forest inventory must be applied. Where such procedures are not available, QA/QC procedures from published handbooks, or from the IPCC, 2003 *Good Practice Guidance for Land Use, Land Use Change and Forestry* (or the most recent version of IPCC good practice guidance for AFOLU) must be applied.
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$FC_{p,j,k,t}$
Data unit	Kg fuel
Description	Fuel consumption by type k, machine type *j*, parcel grassland *p*, in year t under project
Equations	39
Source of data	Project records
Description of measurement methods and procedures to be applied	Record fuel consumption by type *k*, machine type *j*, parcel grassland *p* of each household.
Frequency of monitoring/recording	Record fuel consumption just after the application of machine.
QA/QC procedures to be applied	Guidance provided in IPCC, 2003 chapter 5 or IPCC, 2000 chapter 8 must be applied
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$A_{P,j,s,t}$
Data unit	Ha
Description	Area of trees and shrubs of species *j* in stratum *s* under project in year *t*
Equations	41
Source of data	Project records
Description of measurement methods and procedures to be applied	Maps, orthorectified images, or field-based GPS measurements must be applied. Horizontal projected area required.
Frequency of	Annually, at the beginning of growing season in year t

monitoring/recording	
QA/QC procedures to be applied	Where the difference between the recorded area of trees and shrubs and the new reading is more than 10 percent, reasons for the difference must be discussed with the staff responsible for taking both measurements, and if necessary the area of trees and shrubs should be re-measured.
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$PA_{m_G,s,t}$
Data unit	Ha
Description	Project areas of grassland with management practice *Mg* in stratum *s* in year *t*
Equations	44 and 47
Source of data	Project records
Description of measurement methods and procedures to be applied	Record the area of grassland with management practice *Mg* in stratum *s*.
Frequency of monitoring/recording	Record the area and management practice just after the management practice has taken place and report annually
QA/QC procedures to be applied	Guidance provided in IPCC, 2003 chapter 5 or IPCC, 2000 chapter 8 must be applied
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$SOC_{m_G,s,i,t}$
Data unit	g C/kg soil
Description	SOC stock in the top 30 cm of soil (or greater depth if required) for management practice m_G, stratum *s* (or greater depth if desired), sampling site *i*
Equations	45
Source of data	Project records
Description of measurement methods and procedures to be applied	Measurement methods and procedures described in Section 8.2.8 of this methodology must be applied.
Frequency of	At least once every five years, at the end of growing season in

monitoring/recording	the year measured, until the end of the project crediting period
QA/QC procedures to be applied	Soil sampling, sampling intensity, handling and storage, processing and measurement of $SOC_{m_G,s,i,t}$, and quality control must follow the guidance, methods and procedures as described in Section 8.2.8 of this methodology.The collection of soil samples for measuring SOC must be carried by suitably trained staff. The measurement of SOC must be carried out by a laboratory that can demonstrate adherence to the principles of good laboratory practices, outlined in OECD (1998).
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$BD_{m_G,s,i,t}$
Data unit	g soil/cm^3
Description	Soil bulk density in the top 30 cm of soil (or greater depth if required) for management practice m_G, stratum *s* (or greater depth if desired), sampling site *i*
Equations	45
Source of data	Project records
Description of measurement methods and procedures to be applied	Measurement methods and procedures described in Section 8.2.8 of this methodology must be applied.
Frequency of monitoring/recording	At least once every five years, at the end of growing season in the year measured, until the end of the project crediting period
QA/QC procedures to be applied	Soil sampling, sampling intensity, handling and storage, processing and measurement of $BD_{m_G,s,i,t}$, and quality control must follow the guidance, methods and procedures as described in Section 8.2.8 of this methodology. The collection of soil samples for measuring soil bulk density must be carried by suitably trained staff. The measurement of soil bulk density must be carried out by a laboratory that can demonstrate adherence to the principles of good laboratory practices, outlined in OECD (1998).
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$FC_{m_G,s,i,t}$

Data unit	percent
Description	Percentage of rocks with a diameter larger than 2mm, roots, and other dead residues in the top 30 cm of soil (or greater depth if desired), for management practice m_G, stratum *s*, sampling site *i*
Equations	45
Source of data	Project records
Description of measurement methods and procedures to be applied	Measurement methods and procedures described in Section 8.2.8 of this methodology must be applied.
Frequency of monitoring/recording	At least once every five years, at the end of growing season in the year measured, until the end of the project crediting period
QA/QC procedures to be applied	Soil sampling, sampling intensity, handling and storage, processing and measurement of $FC_{m_G,s,i,t}$, and quality control must follow the guidance, methods and procedures as described in Section 8.2.8 of this methodology. The collection of soil samples for measuring $FC_{m_G,s,i,t}$ must be carried by suitably trained staff. The measurement of $FC_{m_G,s,i,t}$ must be carried out by a laboratory that can demonstrate adherence to the principles of good laboratory practices, outlined in OECD (1998).
Purpose of data	Calculation of project emissions
Comments	

Data Unit / Parameter	$Depth$
Data unit	cm
Description	Total soil depth, for calculating grassland SOC stock in the top 30 cm of soil (or greater depth if required)
Equations	45
Source of data	Project records
Description of measurement methods and procedures to be applied	The value for soil depth must be consistent with the measurements taken. Soil properties must be measured to the full depth of affected soil layers. Where the full depth of affected soil layers is not known, a minimum depth of 30 cm must be applied.
Frequency of monitoring/recording	Recorded with each measurement taken

QA/QC procedures to be applied	
Purpose of data	Calculation of project emissions
Comments	

9.3 Description of the Monitoring Plan

The monitoring plan must include a statement of the purpose(s) of monitoring, and describe monitoring procedures adequate for obtaining, recording, compiling and analyzing data and information important for quantifying and reporting GHG emissions and/or removals relevant for the project (including leakage) and baseline scenario and for meeting any other stated purposes of monitoring. All data collected as part of monitoring must be archived electronically and be kept at least for two years after the end of the project crediting period.

9.3.1 Monitoring of Project Implementation

Information must be provided, and recorded in the project description to establish:

- A record of the grazing agents (eg, herder households) involved the project.
  - The project proponent should record each household involved in the sustainable grassland management project.
  - Each household should be given a unique ID. Their name, location of their land, and date of entering into the agreement and leaving the agreement should be recorded.
- A record of the geographic location of the project area for all areas of grassland;
  - The geodetic coordinates of the project area (and any stratification inside the area) must be established, recorded and archived. This can be achieved by field survey (eg, using GPS), or by using geo-referenced spatial data (eg, maps, GIS datasets).
- A record of grassland management
  - The grassland management plan, together with a record of the plan as actually implemented during the project crediting period must be available for validation and verification.

9.3.2 Validation of Biogeochemical Model

As set out in the applicability conditions, if a biogeochemical model is selected for estimation of change in soil carbon stocks, the model must meet with the requirements for models as set out in the VCS rules.

If a biohgeochemical model is used, it must be validated for the region within which the project is situated based on studies by appropriately qualified experts (eg, scientific journals, university theses, local research studies or work carried out by the project proponent) that demonstrate that the use of the selected biogeochemical model is appropriate. This can be done using one of the approaches described below:

- Approach 1: The studies used in support of the project must meet the guidance on model applicability as set out in the *2006 IPCC Guidelines for National Greenhouse Gas Inventories* in order to show that the model is applicable for the relevant IPCC climatic region. The guidance notes that an appropriate model should be capable of representing the relevant management practices and that the model inputs (ie, driving variables) are validated from country or region-specific locations that are representative of the variability of climate, soil and management systems in the country.
- Approach 2: Where available, national, regional or global level agroecological zone (AEZ) classification can be used to to show that the model has been validated for similar AEZs. It is recognized that national level AEZ classifications are not readily available, and therefore this methodology allows the use of the global and regional AEZ classification.
- Approach 3: Where a project area consists of multiple sites, it is recognized that studies demonstrating model validity using either Approach 1 or Approach 2 may not be available for each of the sites in the project area. In such cases the study used must be capable of demonstrating that the following two conditions are met:
    - o The model is validated for at least 50 percent of the total project area where the project area covers up to and including 50,000 ha; or at least 75 percent of the total project area where project area covers greater than 50,000 ha; and
    - o The area for which the model is validated generates at least two-thirds of the total project emission reductions.

9.3.3 Sampling Design and Stratification (Option 2)

Stratification of the project area into relatively homogeneous units can either increase the measuring precision without increasing the cost unduly, or reduce the cost without reducing measuring precision because of the lower variance within each homogeneous unit.

The project proponent must present in the project description an ex-ante stratification of the project area or justify the lack of stratification. The number and boundaries of the strata defined ex-ante may change during the project crediting period (ex-post). Four main requirements should be met before the stratified sampling is chosen:

- Population must be stratified in advance of the sampling.
- Classes must be exhaustive and mutually exclusive (ie, all elements of the population must fall into exactly one class).
- Classes must differ in the attribute or property under study, otherwise there is no gain in precision over simple random sampling.

- Selection of items to represent each class (ie, the sample drawn from each class) must be random.

Updating of strata

The ex-post stratification must be updated due to the following reasons:

- Unexpected disturbances occurring during the project crediting period (eg, due to fire, pests or disease outbreaks), affecting differently various parts of an originally homogeneous stratum;

- Grassland management activities (planting) may be implemented in a way that affects the existing stratification.

Established strata may be merged if reasons for their establishment have disappeared.

Sampling framework

To determine the sample size of each stratum, the project proponent must use the latest version of the CDM *Tool for the Calculation of the number of sample plots for measurements within A/R CDM project activities*. The targeted precision level for estimation across the project must be a precision of 15 percent at the 95 percent confidence level. Note that although the CDM tool does not allow temporary plots, such plots are permitted under this methodology.

The selection of random points in each stratum has been greatly facilitated by the widespread use of Global Positioning System (GPS) receivers in field research. The points to be sampled can be randomly selected before going to the field, downloaded into the GPS unit, and then the researcher can use the GPS to guide them to that location in the field.

9.3.4 Recording of Data and Parameters Monitored

The following parameters must be record and monitored during the project. When applying the equations provided in this methodology for the *ex-ante* calculation of net anthropogenic GHG removals by sinks, the project proponent must provide transparent estimations for the parameters that are monitored during the project crediting period. These estimates must be based on measured or existing published data where possible and the project proponent must apply a conservative approach: that is, if different values for a parameter are equally plausible, a value that does not lead to over-estimation of net anthropogenic GHG removals by sinks must be selected.

For the estimate of annual emissions from the use of synthetic fertilizers, the following parameters must be recorded at each application during the project crediting period:

- Mass and type of synthetic N fertilizer applied;

- Nitrogen content of synthetic N fertilizer applied.

For the estimate of annual emissions from the burning of grassland, the following parameters must be recorded annually during the project crediting period:

- Annual area of N-fixing species
- Annual dry matter, including aboveground and below ground, returned to grassland soils for N-fixing species
- Fraction of N in dry matter for N-fixing species

For the estimate of annual emissions from the burning of grassland, the following parameters must be recorded at each burning activity during the project crediting period:

- Area burned in year t during the project crediting period
- Aboveground biomass burned exclude litter and dead wood

For the estimate of annual CH_4 emissions from enteric fermentation, population of livestock type *l* and grazing days of livestock type *l* must be recorded annually during the project crediting period.

For the estimate of annual CH_4 and N_2O emissions from manure deposition during grazing, grazing days of livestock of type *l*, and average grazing hours per day of livestock type *l* during the grazing season must be recorded in every grazing season, in each year during the project project crediting period.

For the estimate of annual CO_2 emissions due to the use of fossil fuels for SGM, the following parameters must be recorded at each time a management practice using machines is adopted and reported annually during the project crediting period:

- Quantity of fuel consumption;
- Fuel type;
- Machine type.

For the estimate of annual emissions and removals from woody perennials, the area of trees and shrubs of each stratum must be recorded annually during the project crediting period:

To estimate project removals due to changes in SOC with a validated model, project areas in grassland with different management practice must be recorded.

If option 2 for estimating project removals due to changes in SOC is selected, the following parameters must be monitored at least once every five years during the project crediting period. The soil sampling, handling and storage, processing and measurement, and quality control procedures implemented in soil organic carbon analysis that follow a scientific peer-reviewed or nationally approved standard.

- SOC content;
- Soil bulk density;
- Percentage of rocks with a diameter larger than 2mm, roots and other dead residues;
- Carbonate content.

For the estimate of leakage emissions, the monitoring parameters required in the VCS modules VMD033 *Estimation of Emissions from Market Leakage* and VMD040 *Estimation of Leakage Emissions from Displacement of Grazing Activity due to Implementation of Sustainable Grassland Management Activities* must be recorded annually during the project crediting period.

Methodology for Carpooling

Version 1.0

17 April 2015

Sectoral Scope 7

Methodology developed by: Sohil Thakkar and Wai Cheng

Table of Contents

1 SOURCES

This methodology uses the latest version of the following tool:

- CDM *Tool to calculate the emission factor for an electricity system*

2 SUMMARY DESCRIPTION OF THE METHODOLOGY

Additionality	Project Method
Crediting Baseline	Project Method

This methodology provides procedures to estimate the avoided greenhouse gas (GHG) emissions from using carpools and vanpools for commuting to and from work as facilitated by the use of a carpool management application (CMA). This methodology is applicable only to carpools and vanpools used for commuting purposes; carpools or vanpools used for any other purpose are not eligible. GHG emission reductions are achieved through fewer single-occupancy vehicular trips that rely on fossil fuels or emission-intensive electricity for motive power.

Each carpool member must agree to run a CMA, which is a smartphone application used to track member and carpool vehicle information. The CMA must have the ability to record unique details about each carpool member, including historic routes to and from work and start and end points of commutes. Finally, the CMA must report trip details to a carpool server for occupancy and carpool membership detection and validation. Carpool servers hold the database of information relayed from the CMA about all carpool members and carpool trips.

Baseline emissions are quantified based upon the single-occupancy vehicular trips that would have taken place in the absence of the carpool. Project emissions are quantified by estimating the fuel consumption of eligible carpool trips. Monitoring is primarily based on the CMA's recordation of information about carpool members and trips.

3 DEFINITIONS

3.1 Defined Terms

In addition to the definitions set out in VCS document *Program Definitions*, the following definitions apply to this methodology:

Baseline Emission Quantification Co-efficient (BEQC)
A number between 0 and 1 that represents how often a carpool member commutes by driving alone in the baseline scenario, assigned to a carpool member based on their commuting practice before joining the carpool program. BEQC adjusts the baseline emissions of a carpool member based on past commuting practice.

Carpool

A group of two or more people who share one or more vehicles during any part of their journey to and/or from work. Where referred to in this methodology, carpools also includes vanpools.

Carpool Management Application (CMA)

A software application that runs on a carpool member's smartphone, and that monitors and records trip information and reports it to the carpool server

Carpool Management and Monitoring System (CMMS)

A system consisting of carpool servers, smartphones running a CMA and OBDII dongles, which collectively enable carpool formation, management and GHG emissions monitoring

Carpool Member (Member)

An individual who participates in a carpool by providing rides with a carpool vehicle, receiving a ride from other carpool members, or both

Carpool Server (CS)

A computer system that records and manages data received from a CMA

Carpool Sub-trip

One of the following types of car trip:

- A trip by a carpool vehicle taken by one or more members of the carpool to reach a designated pick-up location
- A multi-occupancy trip by a carpool vehicle taken by members to the pick-up location of other member(s), or to the designated drop off location of one or more members, or both
- A trip by a carpool vehicle taken by the last member or members of a carpool to their final destination

Carpool Trip

The combination of one or more carpool sub-trips taken by members of a carpool to reach their final destination(s) from their point(s) of origin

Carpool Vehicle

A vehicle used in at least one carpool sub-trip

Community Area

A pre-defined geographic area(s) within which carpool activity monitoring takes place (eg, *Very Large Urban Area* and *Large Urban Area* as defined by Texas A&M Transportation Institute). The defined geographic area(s) need not be connected.

Fampool

A carpool consisting of carpool members who all reside within 200 meters of each other and commute to the same work address, or where all carpool members reside at the same residential address and commute to work addresses that are within 200 meters of each other

Fossil Fuel Vehicle (FFV)

A vehicle that relies on fossil fuel as a fuel source (eg, vehicles powered by gasoline, diesel, ethanol-gasoline mixed (E85) or compressed natural gas). Hybrid vehicles using fossil fuel as the single fuel source with regenerative braking to charge the battery are also included in this definition.

Herfindahl-Hirschman Index (HHI)

An indicator of the amount of competition among commuting modes within a specific community area derived from the market share of each commuting mode. The market share of a commuting mode is determined by the number of commuters using that commuting mode relative to that of all commuting modes within the community area.

On-Board Diagnostics II (OBDII)

On-Board Diagnostics specification, version 2 in North America. For this methodology, equivalent standards in Europe (European On Board Diagnostics - EOBD), Japan (Japan On Board Diagnostics – JODB) and Australia (Australian Design Rule 79/01-79/02, Australian OBD standard) are also referred to as OBDII. Additional standards are accepted under this definition if, at a minimum, the Vehicle Identification Number (VIN) can be directly obtained from the vehicle engine control unit (ECU).

OBDII Dongle

A device attached to the carpool vehicle’s OBDII port that allows other devices to wirelessly connect to it and access the vehicle OBDII port. Wireless connection uses short range wireless technologies such as Bluetooth or WiFi. If a vehicle manufacturer traditionally supports wireless access to the vehicle ECU using Bluetooth or WiFi without the use of an externally connected OBDII dongle, such mechanism is also referred to as an OBDII dongle for the purpose of this methodology.

Plug-in Electric Vehicle (PEV)

A vehicle that runs on electric energy stored in on-board batteries and has no other source of external energy to propel the vehicle. Batteries are charged via electricity from the grid.

Plug-in-Hybrid Electric Vehicle (PHEV)

A vehicle that is similar to a plug-in electric vehicle, but also has a fuel tank to power the vehicle beyond the battery charge. The vehicle runs on the battery until the charge is lost, at which point the vehicle runs on an internal combustion engine and the battery to propel the vehicle. The battery may be charged through regenerative braking.

Pre-program Carpool Co-efficient (PCC)

A number between 0 and 1 that represents how often a carpool member commutes by carpooling in the baseline scenario, assigned to a carpool member based on their commuting practice before joining the carpool program

Residential Address

The address of a carpool member's residence, or address of a transit stop to which the carpool member travels and then drives to their work place in the baseline scenario

Single-Occupancy Baseline Trip Distance

The distance of the single-occupancy vehicular trip a member of a carpool would have taken in the baseline scenario. The distance of such trip is calculated as the shortest time or distance between commute start and endpoints as specified in Section 8.1.2.

Single-Occupancy Baseline Trip Vehicle

The vehicle that would be used by a member of a carpool for a single-occupancy vehicular trip in the baseline scenario

Work Address

The address of a carpool member's work place, or address of a transit stop to which a carpool member drives and then takes a follow-on journey on a transit system to their work place in the baseline scenario

4 APPLICABILITY CONDITIONS

This methodology applies to project activities that reduce GHG emissions by using carpools for commuting to and from work, as facilitated by the use of a CMMS that enables a community of people to more effectively engage in carpooling.

This methodology is applicable under the following conditions:

1) Each carpool member must be registered with a CMMS and be uniquely identified via smartphone identity (eg, IMEI and/or phone number). The carpool member's residential address, work address and single-occupancy baseline trip (SOBT) vehicle must be registered and confirmed by the user biennially through the CMA.
2) All carpool vehicles must support OBDII interface.
3) Each carpool member must run a CMA during all carpool trips.
4) Each carpool member must own a private vehicle that is available for their commute and register that vehicle with the CMMS.
5) Each carpool sub-trip must start and end within one of the defined community areas, though the start and end community area may be different and need not be connected.

5 PROJECT BOUNDARY

The sources of GHG emissions included within the project boundary are (1) emissions from burning of fossil fuels by fossil fuel vehicles (FFVs) and plug-in-hybrid electric vehicles (PHEVs), (2) indirect emissions from off-site generation of electricity required for charging plug-in electric vehicles (PEVs) and PHEVs, and (3) indirect emissions from off-site generation of electricity required to run the carpool server(s). The GHG sources included in and excluded from the project boundary are shown in Table 1 below.

The spatial extent of the project boundary encompasses carpool vehicles and carpool servers. Not all carpool members need to be specifically identified at the project start date. For example, a project could be defined as "the first 10,000 members in the Boston metro area" or "employees of Company X in the San Francisco Bay area, Atlanta metro area, and Boston metro area".

Table 1: GHG Sources Included in or Excluded from the Project Boundary

Source		Gas	Included?	Justification/Explanation
Baseline	Fossil fuel emissions from FFVs and/or PHEVs used in SOBTs	CO_2	Yes	Main emission source in the combustion of fossil fuel and electricity generation.
		CH_4	No	Minor source excluded for simplification; this is conservative

Source		Gas	Included?	Justification/Explanation
		N_2O	No	Minor source excluded for simplification; this is conservative
		Other	No	Not applicable
	Indirect fossil fuel emissions from electricity generation used for charging PHEVs and/or PEVs used in SOBTs	CO_2	Yes	Main emission source in the combustion of fossil fuel.
		CH_4	No	Minor source excluded for simplification; this is conservative
		N_2O	No	Minor source excluded for simplification; this is conservative
		Other	No	Not applicable
Project	Fossil fuel emissions from FFVs and/or PHEVs used in carpool trips	CO_2	Yes	Main emission source in the combustion of fossil fuel and electricity generation.
		CH_4	No	Minor source excluded for simplification.
		N_2O	No	Minor source excluded for simplification.
		Other	No	Not applicable
	Indirect fossil fuel emissions from electricity generation used for charging PHEVs and/or PEVs used in carpool trips	CO_2	Yes	Main emission source in the combustion of fossil fuel for electricity generation.
		CH_4	No	Minor source excluded for simplification.
		N_2O	No	Minor source excluded for simplification.
		Other	No	Not applicable
	Indirect fossil fuel emissions from electricity generation used for running the carpool servers	CO_2	Yes	Main emission source in the combustion of fossil fuel for electricity generation.
		CH_4	No	Minor source excluded for simplification.
		N_2O	No	Minor source excluded for simplification.
		Other	No	Not applicable

6 BASELINE SCENARIO

The baseline scenario is the most likely means by which a carpool member would have made their commute (ie, the trip from their residential address to their work address, and the trip from their work address to their residential address) in the absence of the project. To identify the most likely means by which a carpool member would have made their commute in the absence of the project, the commuting modes used in the last 12 months by the carpool member must first be specified at the time of registration with the CMMS. Such data must be updated where a member's work address, residential address or commuting vehicle ownership status changes. The carpool member must attest that all data provided is true, accurate and complete in all material respects. This attestation may be included as part of the terms and conditions of using the application or any other appropriate means.

Assuming members have had their current work and residential addresses for the last 12 months, the following information must be collected with respect to each season[1]:

a) Average number of (fractional) days per week commuting by driving alone

b) Average number of (fractional) days per week commuting by carpooling

c) Average number of (fractional) days per week using an alternative transport mode (ie, public transit, taxicab, motorcycle, walking and bicycling) to commute

d) Average number of (fractional) days per week working from home

The steps below use the information gathered above to establish the baseline transport mode for the carpool member.

Step 1. Determination of PCC and BEQC

Determine PCC and BEQC for the carpool member using the following:

$$PCC_i = \frac{\sum_m C_{i,m}}{5 * M} \tag{1}$$

$$BEQC_i = \frac{\sum_m S_{i,m}}{5 * M} \tag{2}$$

Where:

PCC_i Pre-program carpooling co-efficient of carpool member i

[1] Seasons must be defined according to local climate. For example, spring, summer, fall and winter months (ie, March-May, June-Aug, Sept-Nov, Dec-Feb respectively) could be used as a demarcation of seasons for projects located in the Northeastern United States.

$BEQC_i$ Baseline emission quantification co-efficient of carpool member i

m Season identifier (eg, spring, summer, fall and winter)

M Number of seasons

i Individual carpool member identifier

$C_{i,m}$ Number of days per 5-day week that carpool member i carpools during season m

$S_{i,m}$ Number of days per 5-day week that carpool member i commute by driving alone during season m

Step 2. Determine the most likely means by which a carpool member would have made their commute in the absence of the project (ie, *driving alone*, *carpool*, *periodic carpool*, *alternative transport mode* or *work from home*), based on the following criteria:

a) Where an alternative transport mode (eg, public transit, walking or bicycling) is available, and travel time with such alternative is no more than 15 minutes longer than driving alone, as determined using mapping software such as Google Maps[2] (see Annex 1 for additional requirements on using Google Maps or similar software), the baseline transport mode for the member is *alternative transport mode*.

b) Where a carpool member does not register their commuting vehicle or does not own one, the baseline transport mode for the member is *alternative transport mode*.

c) Where a member's BEQC is less than 0.2, the baseline transport mode for the member is *work from home*.

d) Where a member's PCC is greater than BEQC, it is assumed that the member carpools periodically in the baseline scenario, and the baseline transport mode for the member is *periodic carpool*.

e) Where a member's PCC is greater than or equal to 0.8, it is assumed that the member always carpools in the baseline scenario, and the baseline transport mode for the member is *carpooling only*.

f) Where a member's BEQC is greater than or equal to PCC, the baseline transport mode for the member is *driving alone.*

Only individuals whose baseline scenario is *driving alone* or *periodic carpool* may be included in the project; all other individuals must be excluded from the quantification of emission reductions.

Note that an ineligible member's participation in any sub-trip does not render the entire sub-trip ineligible; eligible members included in such sub-trip may still be included in the quantification of emission reductions. In addition, where a previously ineligible member demonstrates that their commuting practices in the past 12 months have changed such that they now exhibit an eligible baseline scenario, such members may be added to the project.

[2] Software available at www.google.com/maps

7 ADDITIONALITY

This methodology uses a project method for demonstrating and assessing additionality of the project. The project proponent must follow the three-step procedure set out below for this purpose. Where multiple community areas are included in the project, a separate analysis must be undertaken for each community area and only community areas meeting the criteria set out below may be included as part of the project.

Step 1. Regulatory Surplus

The project proponent must demonstrate regulatory surplus in accordance with the rules and requirements regarding regulatory surplus set out in the latest version of the *VCS Standard.*

Where carpooling is not mandated by relevant laws, statutes, policies or other regulatory frameworks within the community area, proceed to Step 2. Where carpooling is mandated by relevant laws, statues or other regulatory frameworks within the community area, the project activity is not additional.

Step 2. Implementation Barriers

Carpooling as facilitated by use of a CMMS within a community area may face a variety of barriers to implementation. The project proponent must demonstrate the existence of one or more barriers that it faces and describe how the additional revenues associated with the sale of VCUs can help to overcome the barrier. The *VCS Standard* sets out three types of barriers, and the project proponent should identify and describe only the relevant and credible barriers they face from the list below:

- Investment barriers (eg, lack of funding for the development and implementation of application software purposed for the formation of carpool programs; sources of capital investment for similar project activities have primarily been from grants or on other non-commercial finance terms)
- Technological barriers (eg, development of software solution to facilitate the formation of carpool programs faces greater implementation risks than conventional approaches to carpool formation; novelty and complexity of software solution increases development risks)
- Institutional barriers (eg, limited inherent interest in carpooling from individuals or companies, due to low desirability of carpooling; lack of incentives to encourage a shift in commuting practices from driving alone to carpooling (eg, employer does not provide dedicated parking spot for carpool vehicles))

Where the project proponent demonstrates the existence of one or more barriers within a community area, and is able to describe how the additional revenues associated with the sale of VCUs can help to overcome the barrier, proceed to Step 3. Where the project proponent is not able to demonstrate the existence of at least one barrier within the community area, the project activity is not additional.

Step 3. Common Practice

The following two steps must be followed to demonstrate that the project activity is not common practice within a community area:

Step 3-A. Demonstration of Dominant Commuting Modes within a Community Area

Step 3-a is completed by calculating a Herfindahl-Hirschman Index (HHI)[3], which is used in economics to measure market competitiveness. The HHI must be used to determine whether the market (potential commuting modes within the community area) is an oligopoly or monopoly market dominated by few commuting modes. An HHI value of 2,500 or higher indicates that there are dominant commuting modes within a community area.

$$HHI = \sum M_k^2 \quad \textbf{(3)}$$

Where:

HHI Measurement of market competiveness

M_k Percentage market share of commuting mode k (percent)

Percentage market share of a commuting mode must be established using data from a recognized, credible source and such data must be reviewed for publication by an appropriately qualified, independent organization or appropriate peer review group, or be published by a government agency.

Step 3-B. Demonstration that Carpooling is Not a Dominant Commuting Mode within a Community

Step 3-b must be completed using the square of market share values for various commuting modes. Specifically, a mode is a dominant mode where:

1) The mode has the highest market share of all modes; or
2) The sum of the square of the market shares of all the modes with market share greater than the mode in question is <2,500. For example, in a community area where mode A represents 40 percent of the commuting practices and mode B represents 60 percent of the commuting practices, to determine whether mode A is a dominant mode, all modes with larger market share (ie, mode B) must be squared and added together. In this

[3] Herfindahl index (HHI): http://www.justice.gov/atr/public/guidelines/hhi.html

example, 60^2 is 3600, which is greater than 2,500, meaning that mode A is not a dominant mode.

If carpooling is not a dominant commuting mode, it is not considered common practice.

To illustrate step 3 above, using the online tool on the United States census website[4] and data from the *2012 American Community Survey 1-year Estimate, for New York-Northern New Jersey-Long Island NY-NJ-PA metro area* study, the market share of different commuting modes in the NY-NJ-PA metro area may be derived, as shown in Table 2 below.

Table 2: Data from 2012 American Community Survey 1-year Estimate for New York-Northern New Jersey-Long Island metro area

	New York-Northern New Jersey-Long Island, NY-NJ-PA Metro Area	
	Estimate	**Margin of Error**
Total:	8,822,701	+/-28,922
Car, truck, or van:	4,989,077	+/-32,665
Drove alone	4,394,811	+/-30,999
Carpooled:	594,266	+/-16,108
In 2-person carpool	440,494	+/-14,236
In 3-person carpool	82,577	+/-5,349
In 4-or-more-person carpool	71,195	+/-5,307
Public transportation (excluding taxicab)	2,739,141	+/-22,580
Walked	538,986	+/-13,357
Taxicab, motorcycle, bicycle, or other means	191,038	+/-8,080
Worked at home	364,459	+/-9,627

Using the data in Table 2 above, and by converting numerical values into percentages, ignoring error margin and combining all “carpooled” types, the percentage market share of each commuting mode may be derived, as shown in Table 3 below.

Table 3: Percentage market share of commuting modes in NY-NJ-PA metro area

NY-NJ-PA Metro	Percentage
Drove alone	49.81%
Public transportation (excluding taxicab)	31.05%
Carpooled	6.74%

[4] US Census online tool: http://factfinder2.census.gov/faces/nav/jsf/pages/index.xhtml

Walked	6.11%
Worked at home	4.13%
Other means	0.90%
Taxicab	0.63%
Bicycle	0.57%
Motorcycle	0.06%
Total:	100%

Using the percentage market share of each commuting mode, an HHI of 3,546 for commuting modes in the NY-NJ-PA metro area can be calculated, as illustrated below.

$$HHI_{ny} = \sum 49.8^2 + 31^2 + 6.74^2 + 6.11^2 + 4.13^2 + .9^2 + .63^2 + .57^2 + .06^2 = 3546$$

Since the HHI is greater than 2,500, this indicates that there are dominant commuting modes within the NY-NJ-PA metro area (step 3-a). In addition, since the sum of the square of the market shares of all the modes with market share greater than carpooling is >2500 ($49.8^2 + 31^2 = 3441$), carpooling is not considered a dominant mode (step 3-b).

Where the project proponent demonstrates that carpooling is not common practice in the community area, the project is additional. Where the project proponent is not able to demonstrate that the project is not common practice, the project activity is not additional.

8 QUANTIFICATION OF GHG EMISSION REDUCTIONS AND REMOVALS

8.1 Baseline Emissions

The baseline emissions of a specific carpool trip are calculated after the trip has been completed. The identity of carpool members who participated in a carpool trip must be recorded by the CMMS, and the baseline emissions are calculated assuming that in the absence of the carpool trip, each eligible carpool member would have undertaken a SOBT. Baseline emissions for a specific carpool trip are calculated by summing emissions from all carpool trips.

8.1.1 Carpool Membership Set

For each carpool trip, the carpool membership set consists of people who travelled together in at least one carpool sub-trip. Each carpool member of the set must be uniquely identified in the CMMS by an assigned number linked to their smartphone (eg, International Mobile Equipment Identity (IMEI), ESN, Mobile Equipment Identifier (MEID)), username and password, a security association (eg, Facebook login token) and/or phone number.

$$N_{y,t} = \bigcup_{j \in S_{y,t}} N_j \qquad (4)$$

Where:

$N_{y,t}$ Membership set of a carpool associated with carpool trip *t* in year *y*

$S_{y,t}$ Set of carpool sub-trips in carpool trip *t* in year *y*

N_j Carpool sub-trip j membership set (ie, set of occupants *i* on sub-trip *j*)

j Particular carpool sub-trip identifier

i Individual carpool member identifier who travelled in trip *t* in year *y*

8.1.2 Baseline Emissions Estimate for a Member of a Carpool Trip

In the absence of the carpool trip, it is assumed that each member of the carpool would have taken two individual, single-occupancy car trips. The first would be from their registered residential address to their registered work address, and the second would be to their registered residential address from their registered work address. Each of these individual trips is called a Single-Occupancy Baseline Trip (SOBT). Note that baseline emissions must be quantified separately for the trip to work and for the trip from work.

For each member in the carpool trip membership set, SOBT emissions ($BE_{i,ć}$) are the summation of emissions from fossil fuel consumption in the SOBT vehicle, and indirect emissions from electricity generation used for charging the SOBT vehicle.

The SOBT trip must be defined at the time of registration with the CMMS, and when a member updates their residential or work address. The SOBT trip must be defined as the route taking the least amount of time and which does not account for traffic. Where the CMMS is capable of obtaining the route which takes the least amount of time each time a member makes a carpool trip, such dynamic SOBT trip may be used as an alternative.

Where the carpool member's registered SOBT vehicle is a PEV, the equation below must be used to estimate the carpool member's baseline emissions:

$$BE_{i,ć} = D_i \cdot W_{ć} \cdot GE_p \qquad (5)$$

Where:

$BE_{i,ć}$ Baseline emissions for carpool member *i* in SOBT vehicle $ć$ (tCO_2e)

i Identifier for carpool member

D_i SOBT distance for carpool member i (km)

$W_{ć}$ Electric efficiency for SOBT vehicle identified by VIN number $ć$ (kWh/km)

GE_p Electricity generation GHG emission factor corresponding to project community area *p*, adjusted for transmission loss, if available (tCO_2e/kWh)

Where the carpool member's registered SOBT vehicle is an FFV, the equation below must be used to estimate the carpool member's baseline emissions:

$$BE_{i,\acute{c}} = D_i \cdot V_{\acute{c}} \cdot EF_{f(c)} \tag{6}$$

Where:

$BE_{i,\acute{c}}$ Baseline emissions for carpool member *i* in SOBT vehicle $\acute{c}$ (tCO_2e)

i Identifier for carpool member

D_i SOBT distance for carpool member i (km)

$V_{\acute{c}}$ Vehicle fossil fuel efficiency for SOBT vehicle $\acute{c}$ (L/km)

$EF_{f(c)}$ GHG emission factor of fuel used by vehicle identified by VIN number *c* (tCO_2e/L)

$\acute{c}$ VIN of SOBT vehicle

Where the carpool member's registered SOBT vehicle is a PHEV, the equation below must be used to estimate the carpool member's baseline emissions:

$$BE_{i,\acute{c}} = max(0, D_i - R_{\acute{c}}) \cdot V_{\acute{c}} \cdot EF_{f(c)} + min(D_i, R_{\acute{c}}) \cdot W_{\acute{c}} \cdot GE_p \tag{7}$$

Where:

$BE_{i,\acute{c}}$ Baseline emissions for carpool member *i* in SOBT vehicle $\acute{c}$ (tCO_2e)

i Identifier for carpool member

D_i SOBT distance for carpool member i (km)

$R_{\acute{c}}$ Vehicle all-electric range for SOBT vehicle identified by VIN $\acute{c}$ (km)

$W_{\acute{c}}$ Vehicle electric efficiency for SOBT vehicle identified by VIN $\acute{c}$ (kWh/km)

GE_p Electricity generation GHG emission factor corresponding to project community area p, adjusted for transmission loss, if any (tCO_2e/kWh)

$V_{\acute{c}}$ Vehicle fossil fuel efficiency for SOBT vehicle $\acute{c}$ (L/km)

$EF_{f(c)}$ GHG emission factor of fuel used by vehicle identified by VIN number c ($tCO_2e/liter$)

$\acute{c}$ VIN of SOBT vehicle

8.1.3 Baseline Emissions for a Carpool Trip

The baseline emissions for a carpool trip are estimated as the summation of baseline emissions for each carpool member that participated in the carpool trip as follows:

$$BE_{y,t} = \sum_{i \in N_{y,t}} BEQC_i \cdot BE_{i,ć} \tag{8}$$

Where:

$BE_{y,t}$ Baseline emissions for a carpool trip *t* in year *y* (tCO_2e)

$N_{y,t}$ Membership set of a carpool associated with the carpool trip t in year y

$BEQC_{i,}$ Baseline emission quantification co-efficient of carpool member

$BE_{i,ć}$ Baseline emissions for carpool member *i* in SOBT vehicle $ć$ (tCO_2e)

$ć$ VIN of SOBT vehicle

8.1.4 Baseline Emissions for Year *y*

Baseline emissions for year *y* are calculated by summing the baseline emissions of all carpool trips taken in year *y*.

$$BE_y = \sum_{t \in T_y} BE_{y,t} \tag{9}$$

Where:

BEy Baseline emissions for year *y* (tCO_2e)

T_y Set of all carpool trips in year *y*

$BE_{y,t}$ Baseline emissions for a carpool trip *t* in year *y* (tCO_2e)

8.2 Project Emissions

Project emissions are calculated from monitored data for each carpool trip. Project emissions for a specific carpool trip are calculated by summing emissions from all carpool sub-trips.

The emissions from each carpool sub-trip ($PE_{j,c}$) are estimated as the summation of emissions from burning fossil fuels in carpool vehicles and indirect emissions from electricity generation used for charging carpool vehicles. Note that project emissions must be quantified separately for the trip to work and for the trip from work.

A carpool trip where the carpool vehicle's internal systems are not functioning properly, as indicated by the check engine light or Malfunction Indicator Light (MIL) being on, or where the carpool vehicle does not have the OBDII dongle attached to its OBD port, is not eligible to be included in the quantification of emission reductions.

Where the carpool vehicle is a PEV, the equation below must be used to estimate project emissions for the carpool sub-trip *j*:

$$PE_{j,c} = d_j \cdot W_c \cdot GE_p \qquad (10)$$

Where:

$PE_{j,c}$ Project emissions for carpool sub-trip *j* in vehicle identified by VIN number *c* (tCO_{2e})

j Unique carpool sub-trip numerical identifier, assigned in a way so that current sub-trip identifier is greater than that of all previous sub-trips within this carpool trip

d_i CMA measured travel distance of carpool sub-trip *j* (km)

$W_ć$ Vehicle electric efficiency of a carpool vehicle identified by VIN number *c* (kWh/km)

GE_p Electricity generation GHG emission factor corresponding to project community area p, adjusted for transmission loss, if any (tCO_2e/kWh)

c VIN of carpool vehicle used in sub-trip *j*

Where the carpool vehicle is an FFV, and a fossil fuel consumption measurement is available over the OBDII interface during carpool sub-trip *j*, the equation below must be used to estimate project emissions for the carpool sub-trip *j*:

$$PE_{j,c} = FC_{j,c} \cdot EF_{f(c)} \qquad (11)$$

Where:

$PE_{j,c}$ Project emissions for carpool sub-trip *j* in vehicle identified by VIN number c (tCO_2e)

j Unique carpool sub-trip numerical identifier, assigned in a way so that current sub-trip identifier is greater than that of all previous sub-trips within this carpool

$EF_{f(c)}$ GHG emission factor of fuel used by vehicle identified by VIN number *c* (tCO_2e /liter)

$FC_{j,c}$ Measured fuel consumption (or cubic feet for natural gas) over OBDII interface during carpool sub-trip j for a carpool vehicle identified by VIN number *c* (liters)

c VIN of carpool vehicle used in sub-trip *j*

Where the carpool vehicle is an FFV, but a fossil fuel consumption measurement is not available over the OBDII interface during carpool sub-trip *j*, the equation below must be used to estimate project emissions for the carpool sub-trip *j*:

$$PE_{j,c} = d_j \cdot V_c \cdot EF_{f(c)} \qquad (12)$$

Where:

$PE_{j,c}$ Project emissions for carpool sub-trip *j* in vehicle identified by VIN number *c* (tCO_2e)

j Unique carpool sub-trip numerical identifier, assigned in a way so that current sub-trip identifier is greater than that of all previous sub-trips within this carpool

d_j CMA measured travel distance of carpool sub-trip *j* (km)

V_c Vehicle fossil fuel efficiency of a carpool vehicle identified by VIN number *c*, (L/km)

$EF_{f(c)}$ GHG emission factor of fuel used by vehicle identified by VIN number *c* (tCO_2e/L)

c VIN of carpool vehicle used in sub-trip *j*

Where the carpool vehicle is a PHEV, and a fossil fuel consumption measurement is available over the OBDII interface during carpool sub-trip *j*, the equation below must be used to estimate project emissions for the carpool sub-trip *j*:

$$\boldsymbol{PE_{j,c} = FC_{j,c} \cdot EF_{f(c)} + min\left(d_j, \max(0, R_c - dd_{j,c})\right) \cdot W_c \cdot GE_p} \quad (13)$$

Where:

$PE_{j,c}$ Project emissions for carpool sub-trip *j* in vehicle identified by VIN number *c* (tCO_2e)

j Unique carpool sub-trip numerical identifier, assigned in a way so that current sub-trip identifier is greater than that of all previous sub-trips within this carpool

$FC_{j,c}$ Measured fuel consumption (or cubic feet for natural gas) over OBDII interface during carpool sub-trip *j* for a carpool vehicle identified by VIN number *c* (liters)

$EF_{f(c)}$ GHG emission factor of fuel used by vehicle identified by VIN number *c* (tCO_2e/liter)

d_j CMA measured travel distance of carpool sub-trip *j* (km)

R_c Vehicle all electric range of a carpool vehicle identified by VIN number *c* (km)

$dd_{j,c}$ Cumulative distance travelled by a carpool vehicle c before sub-trip *j* within carpool trip *t* in year *y*

W_c Vehicle electric efficiency of a carpool vehicle identified by VIN number *c* (kWh/km)

GE_p Electricity generation GHG emission factor corresponding to project community area p , adjusted for transmission loss if any (tCO_2e /kWh)

c VIN of carpool vehicle used in sub-trip *j*

Where the carpool vehicle is a PHEV, but a fossil fuel consumption measurement is not available over the OBDII interface during carpool sub-trip *j*, the equation below must be used to estimate project emissions for the carpool sub-trip *j*:

$$PE_{j,c} = \left(\left(d_j - min\left(d_j, \max(0, R_c - dd_{j,c})\right)\right) \cdot V_c\right) \cdot EF_{f(c)} + min\left(d_j, \max(0, R_c - dd_{j,c})\right) \cdot W_c \cdot GE_p \quad (14)$$

Where:

$PE_{j,c}$ Project emissions for carpool sub-trip *j* in vehicle identified by VIN number *c* (tCO_2e)

j Unique carpool sub-trip numerical identifier, assigned in a way so that current sub-trip identifier is greater than that of all previous sub-trips within this carpool

$EF_{f(c)}$ GHG emission factor of fuel used by vehicle identified by VIN number *c* (tCO_2e/liter)

d_j CMA measured travel distance of carpool sub-trip *j* (km)

R_c Vehicle all electric range of a carpool vehicle identified by VIN number *c* (km)

$dd_{j,c}$ Cumulative distance travelled by a carpool vehicle c before sub-trip *j* within carpool trip t in year *y*

W_c Vehicle electric efficiency of a carpool vehicle identified by VIN number *c* (kWh/km)

V_c Vehicle fossil fuel efficiency of a carpool vehicle identified by VIN number *c* (l/km)

GE_p Electricity generation GHG emission factor corresponding to project community area p, adjusted for transmission loss if any (tCO_2 /kWh)

c VIN of carpool vehicle used in sub-trip *j*

Cumulative distance travelled by carpool vehicle c before sub-trip j is determined as follows:

$$dd_{j,c} = \sum_{\{j': j' \in S_{y,t}, C(j')=c, j'<j\}} d_{j'} \quad (15)$$

Where:

$C(j)$ VIN number of vehicle used in sub-trip j

8.2.1 Project Emissions for Carpool Trip

The project emissions for a carpool trip *t* in year *y* ($PE_{y,t}$) are calculated as the summation of the project emissions for each carpool sub-trip *j* included in the carpool trip t as follows:

$$PE_{y,t} = \sum_{j \in S_{y,t}} PE_{j,c} \quad (16)$$

Where:

$PE_{y,t}$ Project emissions for a carpool trip t in year y (tCO_2e)

$PE_{j,c}$ Project emission for carpool sub-trip *j* in vehicle identified by VIN number *c* (tCO_2e)

j Unique carpool sub-trip numerical identifier, assigned in a way so that current sub-trip identifier is greater than that of all previous sub-trips within this carpool

c VIN of carpool vehicle used in sub-trip *j*

8.2.2 Project Emissions from Off-site Generation of Electricity

Project emissions are calculated for the off-site generation of electricity for powering the central carpool server(s), which may or may not be owned and operated by the project proponent, using the equation below:

$$PE_{of,y} = \sum EC_{CS} \cdot GE_p \quad (17)$$

Where:

$PE_{of,y}$ Project emissions for off-site generation of electricity for powering central carpool servers (tCO_2e)

EC_{CS} Electricity consumption by the central carpools server(s) (kWh)

GE_p Electricity generation GHG emission factor corresponding to project community area p, adjusted for transmission loss if any (tCO_2 /kWh)

8.2.3 Project Emissions for Year *y*

Summation over all carpool trips in year *y* provides project emissions for year *y* (PE_y), as follows:

$$PE_y = \sum_{t \in T_y} PE_{y,t} + PE_{of,y} \quad (18)$$

Where:

PE_y Total project emissions for year y (tCO_2e)

$PE_{y,t}$ Project emissions for a carpool trip t in year y (tCO_2e)

$\boldsymbol{PE_{of,y}}$ Project emissions for off-site generation of electricity for powering central carpool servers (tCO_2e)

8.3 Leakage

Leakage is not considered an issue for this methodology, particularly because it is unlikely that individuals would move their commute outside the project boundary due to an increase in carpooling within the project boundary.

$$LE_y = 0 \quad (19)$$

Where:

LE_y Leakage emissions from the project in year *y* (tCO_2e)

8.4 Summary of GHG Emission Reductions and Removals

The net GHG emission reductions are quantified as a function of baseline emissions, project emissions and leakage, and the equation below must be used to estimate net GHG emission reductions for the project in year *y*:

$$ER_y = BE_y - PE_y - LE_y \quad (20)$$

Where:

ER_Y Net GHG emission reductions in year *y*

BE_Y Baseline emissions in year *y*

PE_y Project emissions in year *y*

LE_y Leakage in year *y*

9 MONITORING

9.1 Data and Parameters Available at Validation

Data Unit / Parameter	GE_p
Data unit	Tonnes of CO_2e per kWh
Description	Electricity generation GHG emission factor corresponding to project community area p
Equations	5, 7, 10, 13, 14, 16
Source of data	Data must be from a recognized, credible source and the data must be reviewed for publication by an appropriately qualified, independent organization or appropriate peer review group, or be published by a government agency. The emission calculator from the EPA may be used for projects within the United States: http://www.epa.gov/cleanenergy/energy-resources/refs.html The most recent version of the CDM *Tool to calculate the emission factor for an electricity system* may be used when no published source is available. The project proponent must use the combined margin from this tool with preference being given to the weighted combined margin, if possible. Note that the units from the output of this tool must be converted to match the units of this parameter.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	The United States EPA maintains its calculator based on extensive research
Purpose of data	Calculation of baseline and project emissions
Comments	

Data Unit / Parameter	$EF_{f(c)}$
Data unit	Tonnes of CO_2e per liter

Description	GHG emission factor of fuel used by vehicle identified by VIN *c*
Equations	6, 7, 11, 12, 13, 14
Source of data	Data must be from a recognized, credible source and the data must be reviewed for publication by an appropriately qualified, independent organization or appropriate peer review group, or be published by a government agency. The emission calculator from EPA may be used for projects within the United States: http://www.epa.gov/cleanenergy/energy-resources/refs.html
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	The United States EPA maintains its calculator based on extensive research
Purpose of data	Calculation of baseline and project emissions
Comments	The appropriateness of this value must be reviewed at each project crediting period renewal

Data Unit / Parameter	R_c
Data unit	Kilometers
Description	All electric range of vehicle identified by VIN *c*
Equations	7, 13, 14
Source of data	Manufacturer or government published data. In the United States, values from the following website may be used: http://www.fueleconomy.gov
Valued applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	The government or manufacturer published fuel economy value must be converted to kilometers to match the calculation units. Where city and highway values are provided by the source of the fuel economy data, the average of the two must be used.
Purpose of data	Calculation of baseline and project emissions
Comments	The value of this parameter must be established ex-post if the model of vehicle *c* was not released until after validation or if new vehicle models join the project after validation

Data Unit / Parameter	M_k
Data unit	Percent
Description	Percentage market share of commuting transport mode *k* in the carpool community area
Equations	3
Source of data	Data must be from a recognized, credible source and the data must be reviewed for publication by an appropriately qualified, independent organization or appropriate peer review group, or be published by a government agency. In the United States, the United States Census website may be used: http://factfinder2.census.gov.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	The United States Census is an authoritative source of data. The online tool provides easy access to a specific population's commuting data for customizable geographic areas.
Purpose of data	Demonstration of additionality
Comments	

Data Unit / Parameter:	j
Data unit	Unitless
Description	Unique carpool sub-trip numerical identifier, assigned in a way so that the current sub-trip identifier is greater than that of all previous sub-trips within a specific carpool
Equations	4, 10, 11, 12, 13, 14, 15
Source of data	Member's CMA
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	N/A
Purpose of data	Calculation of baseline and project emissions
Comments	

Data Unit / Parameter	m
Data unit	Unitless

Description	Season identifier
Equations	1, 2
Source of data	Project proponent
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	The project proponent must justify the choice of the number of seasons
Purpose of data	Demonstration of additionality
Comments	

Data Unit / Parameter	p
Data unit	Unitless
Description	Geographic area (community area) within which all or part of carpool or SOBT trip takes place.
Equations	5, 7, 10, 13, 14, 16
Source of data	Project proponent
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	N/A
Purpose of data	Demonstration of additionality
Comments	

9.2 Data and Parameters Monitored

Data Unit / Parameter	V_c
Data unit	Liters per kilometer
Description	Fossil fuel efficiency of carpool vehicle identified by VIN *c*
Equations	12, 14
Source of data	Government or manufacturer public fuel economy statistics
Description of measurement methods and procedures to be applied	The government or manufacturer published fuel economy value must be converted to kilometers to match the calculation units. Where city and highway values are provided by the source of the fuel economy data, the average of the two must

	be used. In the United States, data may be available at: http://www.fueleconomy.gov.
Frequency of monitoring/recording	This parameter must be added when the carpool vehicle of a specific model, make and year is not present in CMMS
QA/QC procedures to be applied	N/A
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comments	The value of this parameter must be established *ex-post* if the model of vehicle *c* was not released until after validation or if new vehicle models join the project after validation

Data Unit / Parameter	W_c
Data unit	kWh per kilometer
Description	Electric efficiency of a carpool vehicle identified by VIN *c*
Equations	10, 13, 14
Source of data	Government or manufacturer public fuel economy statistics
Description of measurement methods and procedures to be applied	The government or manufacturer published fuel economy value must be converted to kilometers to match the calculation units. Where city and highway values are provided by the source of the fuel economy data, the average of the two must be used. In the United States, data available at http://www.fueleconomy.gov may be used.
Frequency of monitoring/recording	This parameter must be added when the carpool vehicle of a specific model, make and year is not present in CMMS
QA/QC procedures to be applied	None
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comments	The value of this parameter must be established *ex-post* if the model of vehicle *c* was not released until after validation or if new vehicle models join the project after validation

Data Unit / Parameter	$FC_{j,c}$

Data unit	Liters
Description	Fossil fuel consumption for sub-trip *j* in vehicle *c*
Equations	11, 13
Source of data	Member's CMA
Description of measurement methods and procedures to be applied	The CMA running on member's smartphone programmatically queries the vehicle's ECU over OBDII interface for various fuel cycle parameters to monitor fossil fuel consumption
Frequency of monitoring/recording	Every carpool sub-trip
QA/QC procedures to be applied	Check documentation supporting appropriateness of method used to calculate fuel consumption
Purpose of data	Calculation of project emissions
Calculation method	Based on reference 1 identified in Section 10 below, or based on a similar calculation method found in a study that was reviewed for publication by an appropriately qualified, independent organization or appropriate peer review group, or published by a government agency
Comments	

Data Unit / Parameter	$V_{\acute{c}}$
Data unit	Liters per kilometer
Description	Fossil fuel efficiency of SOBT vehicle identified by VIN $\acute{c}$
Equations	6, 7
Source of data	There are two possible sources for this parameter, listed in order of preferred use: 1) Average of last 3 months of measured values 2) Government or manufacturer public fuel economy statistics
Description of measurement methods and procedures to be applied	Depending on the capabilities of the OBDII dongle, CMA, carpool member's smartphone and vehicle ECU, if measured values of fuel consumption and trip distance are available, the vehicle fossil fuel efficiency is calculated as the last 3 months of measured fuel consumption divided by trip distance. If measured values are not available, government or manufacturer values may be used. The government or manufacturer published fuel economy value must be converted to kilometers to match the calculation units. Where city and highway values are provided by the source of the fuel

	economy data, the average of the two must be used. In the United States, data may be available at http://www.fueleconomy.gov.
Frequency of monitoring/recording	Where measured values are available, measured fuel efficiency must be updated after every carpool trip of the member. Otherwise, only update when the model, make and year of SOBT vehicle was not present in CMMS.
QA/QC procedures to be applied	Verify that the CMAs and the CS software product is a released product, a released product with a patch or a beta version, and are at least within two major revisions of latest released code version supported on underlying hardware
Purpose of data	Calculation of baseline emissions
Calculation method	Where using the average of 3 months of data, individual values are obtained by dividing $FC_{j,c}$ by d_j
Comments	The value of this parameter must be established *ex-post* if the model of vehicle *c* was not released until after validation or if new vehicle models join the project after validation

Data Unit / Parameter	$W_{\acute{c}}$
Data unit	kWh per kilometer
Description	Electric efficiency of SOBT vehicle identified by VIN $\acute{c}$
Equations	5, 7
Source of data	Government or manufacturer public fuel economy statistics
Description of measurement methods and procedures to be applied	The government or manufacturer published fuel economy value must be converted to kilometers to match the calculation units. Where city and highway values are provided by the source of the fuel economy data, the average of the two must be used. In the United States, data available at http://www.fueleconomy.gov may be used.
Frequency of monitoring/recording	This parameter must be added when the carpool vehicle of a specific model, make and year is not present in CMMS
QA/QC procedures to be applied	N/A
Purpose of data	Calculation of baseline emissions
Calculation method	N/A
Comments	The value of this parameter must be established *ex-post* if the

	model of vehicle *c* was not released until after validation or if new vehicle models join the project after validation

Data Unit / Parameter	d_j
Data unit	Kilometers
Description	Distance travelled during sub-trip *j*
Equations	10, 12, 13, 14
Source of data	One or more members of the CMA
Description of measurement methods and procedures to be applied	The CMA running on each member's smartphone records geodetic coordinates at periodic intervals and reports to the CS as part of the trip report. Alternatively, the CMA may also query the carpool vehicle ECU to obtain the distance traveled.
Frequency of monitoring/recording	Every sub-trip
QA/QC procedures to be applied	N/A
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comments	A carpool trip consists of associated sub-trips reported from one or more CMA. The CMA reports can be used to validate this sub-trip distance parameter.

Data Unit / Parameter	$dd_{j,c}$
Data unit	Kilometers
Description	Cumulative distance travelled by a carpool vehicle c before sub-trip *j* within carpool trip t in year *y*
Equations	13, 14
Source of data	One or more member's CMA
Description of measurement methods and procedures to be applied	The CMA running on each member's smartphone records geodetic coordinates at periodic intervals and reports to the CS as part of the trip report. Alternatively, the CMA may also query the carpool vehicle ECU to obtain the distance traveled.
Frequency of monitoring/recording	Every sub-trip
QA/QC procedures to be applied	N/A

Purpose of data	Calculation of project emissions
Calculation method	Determined as the sum of the distance of all carpool sub-trips prior to the current carpool sub-trip for a given carpool trip
Comments	

Data Unit / Parameter	$S_{i,m}$
Data unit	Unitless
Description	Number of days a carpool member i drove alone during seasons m before registering with carpool program
Equations	2
Source of data	Member registration process
Description of measurement methods and procedures to be applied	Members provide this information at the time of registration. Seasons must be defined according to local climate. For example, spring, summer, fall and winter months (ie, March-May, June-Aug, Sept-Nov, Dec-Feb respectively) could be used as a demarcation of seasons for projects located in the Northeastern United States. Number of days can be whole or fractional number between 0 and 5.
Frequency of monitoring/recording	Once at the time of registration
QA/QC procedures to be applied	Due to cost and privacy concerns, individual member review may not be feasible for validation/verification bodies to perform quality check. Instead, mean, variance and distribution of all or randomly sampled new member registration data for given year may be reviewed to ensure quality.
Purpose of data	Calculation of baseline emissions
Calculation method	N/A
Comments	

Data Unit / Parameter	$C_{i,m}$
Data unit	Unitless
Description	Number of days a carpool member i commuted to work as part of a carpool during seasons m before registering with the carpool program

Equations	1
Source of data	Member registration process
Description of measurement methods and procedures to be applied	Members provide this information at the time of registration. Seasons must be defined according to local climate. For example, spring, summer, fall and winter months (ie, March-May, June-Aug, Sept-Nov, Dec-Feb respectively) could be used as a demarcation of seasons for projects located in the Northeastern United States. Number of days can be whole or fractional number between 0 and 5.

Data Unit / Parameter	c
Data unit	Unitless
Description	VIN of vehicle used for sub-trip j
Equations	10, 11, 12, 13, 14, 15
Source of data	One or more member's CMA
Description of measurement methods and procedures to be applied	A CMA running on a member's smartphone programmatically queries vehicle's ECU over OBDII interface for VIN of the carpool vehicle. Must be queried at periodic intervals and reported to the CS as a part of the trip report. At least one member's CMA must report the VIN of the carpool vehicle in every sub-trip.
Frequency of monitoring/recording	Every sub-trip
QA/QC procedures to be applied	N/A
Purpose of data	Calculation of project emissions

Calculation method	N/A
Comments	A carpool trip consists of associated sub-trip reported from one or more CMA. Examine the CMA report to validate the sub-trip of the carpool vehicle's VIN.

Data Unit / Parameter	N_j
Data unit	Unitless
Description	Set of members i carpooling together in sub-trip j. Each member is identified using meta-data (eg, phone number or username).
Equations	4
Source of data	One or more member's CMA
Description of measurement methods and procedures to be applied	A CMA running on member's smartphone reports the wirelessly detected OBDII dongle ID associated to the carpool vehicle in the trip report. CS determines co-occupancy of members by checking for members who report the same OBDII device ID with appropriate timestamp.
Frequency of monitoring/recording	Every sub-trip
QA/QC procedures to be applied	N/A
Purpose of data	Calculation of baseline emissions
Calculation method	N/A
Comments	A carpool trip consists of associated sub-trip reports from one or more CMA. Examine CMA reports to validate sub-trip membership.

Data Unit / Parameter	D_i
Data unit	Kilometers
Description	Single-occupancy baseline trip distance of member i
Equations	5, 6, 7
Source of data	Mapping or navigational software (eg, Google Maps) or member provided
Description of measurement methods and procedures to be applied	Where CMMS is capable of obtaining the shortest time in-traffic route every time a member makes a carpool trip, such a dynamic SOBT trip distance may be used. Otherwise, SOBT

	trip distance along the shortest time with no traffic route must be used. Where the project proponent can justify that the shortest time distance cannot be established using a mapping software, this parameter may be based on member provided SOBT trip distance at time of registration.
Frequency of monitoring/recording	Where CMMS is capable, this parameter must be determined at start of the carpool trip. Otherwise, it must be determined at the time of registration and again when a member updates their residential or work address.
QA/QC procedures to be applied	N/A
Purpose of data	Calculation of baseline emissions
Calculation method	N/A
Comments	

Data Unit / Parameter	$S_{y,t}$
Data unit	Unitless
Description	Set of sub-trips making up carpool trip t in year *y*
Equations	4
Source of data	One or more member's CMA
Description of measurement methods and procedures to be applied	The CMA running on a member's smartphone records geodetic co-ordinates and/or the detected OBDII device ID attached to the vehicle and corresponding timestamp at periodic intervals for the trip report. Upon receiving the trip report, the CS determines the nature of sub-trip as: carpool multi-occupancy sub-trip, carpool single-occupancy sub-trip or not a carpool sub-trip.
Frequency of monitoring/recording	Every carpool trip
QA/QC procedures to be applied	N/A
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comments	A carpool trip consists of associated sub-trip reports from one or more CMA. Examine all CMA reports to validate carpool trip.

Data Unit / Parameter	i
Data unit	Unitless
Description	CMMS assigned unique identifier for a member
Equations	1, 2, 4, 5, 6, 7
Source of data	Member registration process
Description of measurement methods and procedures to be applied	CMMS-assigned unique identifier for a member identified by username and password, social media security-token (eg, facebook), phone number and/or smartphone IMEI. The information to identify unique members (eg, username and password) must be obtained during registration and stored in CMMS.
Frequency of monitoring/recording	Once at the time of registration with the CMA
QA/QC procedures to be applied	N/A
Purpose of data	Determination of baseline scenario and calculation of baseline emissions
Calculation method	N/A
Comments	

Data Unit / Parameter	$\acute{c}$
Data unit	Unitless
Description	VIN of SOBT vehicle registered to member i
Equations	6, 7, 8
Source of data	Member registration process and/or wirelessly transmitted to the CMA via OBDII dongle
Description of measurement methods and procedures to be applied	During member registration process, where a member owns a private SOBT vehicle, an identifier assigned by CMMS for that SOBT vehicle based on vehicle registration number (ie, vehicle tag plate and/or license plate) and/or year, make, model and/or trim entered by the member. This identifier may be updated to actual vehicle VIN if member uses the same vehicle for carpooling and actual vehicle VIN is reported by CMA.
Frequency of monitoring/recording	At registration with the CMA and updated by the member as necessary.
QA/QC procedures to be	N/A

applied	
Purpose of data	Calculation of baseline emissions
Calculation method	N/A
Comments	Where members do not use their SOBT vehicle for the carpool trips, actual vehicle VIN may not be available to obtain vehicle make, year and model from the VIN number. In such cases, where free or low cost programmatic interface to motor vehicle department registration is available, such facility may be used by project proponent or VVBs to verify the vehicle year, make and model provided by the member during registration.

Data Unit / Parameter	EC_{CS}
Data unit	kWh
Description	Electricity consumption of the central carpools server(s)
Equations	16
Source of data	Project proponent
Description of measurement methods and procedures to be applied	Where the CS hardware is owned and operated by the project proponent, the electricity consumption of the CS is either measured (eg, using an electricity meter), or estimated based on the rated power of the CS and its operating hours. Where the CS hardware is not owned or operated by the project proponent (ie, is deployed in public or private cloud), then the kWh attributable to the CS are estimated based on the server usage (or allocated server sizing) information. In case of public hosting, such information may be obtained from the invoices from the external CS service provider.
Frequency of monitoring/recording	Either monthly or dependent on the frequency of external CS service provider invoices
QA/QC procedures to be applied	Electric meter and usage logs, hardware or CS sizing documentation
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comments	

9.3 Description of the Monitoring Plan

The project proponent must establish, maintain and apply a monitoring plan and GHG information system that includes criteria and procedures for obtaining, recording, compiling and analyzing data, parameters and other information important for quantifying and reporting GHG emissions.

Key data for calculating the baseline and project emissions must be centrally managed and stored by the project proponent.

Each carpool member participating in the project must download the CMA on their smartphone, and provide the following information:

1) Personal identifying information (eg, name, address, phone number, etc)
2) Details of one or more single-occupancy trip (SOBT):
    a) End-points (ie, residential and work addresses)
    b) Vehicle ID (ie, vehicle identification number (VIN))
    c) A carpool vehicle if that vehicle is only used for carpooling (eg, if an employer provided or arranged vans for vanpool).

The CMA running on a carpool member's smartphone must perform the following operations:

1) Detect and record identity of OBDII device in the vehicle. Medium Access Address (MAC address) uniquely identifies each OBDII device (other temper proof IDs may also be used).
2) Calculate and record time, distance and trip endpoints using smartphone geodetic function or querying vehicle ECU over OBDII device
3) When authorized, establish a wireless link to the OBDII device, query and record VIN, create a trip report that includes all required parameters and send it to the carpool server

The CMA may also estimate and record fuel consumption along trip endpoints by reading fuel cycle parameters from vehicle ECU through OBDII device. Depending on available fuel cycle parameters, fuel consumption is estimated using the most suitable method.

Upon receiving a trip report from two or more CMAs, the carpool server must establish the following:

1) The carpool membership set
2) The carpool GHG emissions based on carpool sub-trip's fuel consumption data reported by CMAs
3) Carpool sub-trip distance
4) Vehicle VINs combined with EPA/manufacturer fuel efficiency. Vehicle VIN enables determination of vehicle EPA/manufactures estimated fossil fuel efficiency to estimate fuel consumption when OBDII based fuel consumption is not reliable or feasible.
5) The baseline emissions by assuming SOBT trips in absence of the carpool trip, based on the membership set and their registered SOBTs

All monitored data for emission reduction calculations must be archived in a secure and retrievable manner for at least two years after the end of the project crediting period.

APPENDIX 1: USE OF GOOGLE MAPS OR SIMILAR SOFTWARE

Google Maps provides multiple route options between source and destination addresses with an estimate of travel time in current traffic conditions, travel time with no traffic and travel time with public transportation, walking or biking.

At the time of registration with the CMMS, or when an update to residence and/or work address is enacted by the member, the travel time and distance of the member's commute (ie, the trip from residential address to work, and back) may be obtained using Google Maps or similar software that is capable of providing the same information required by this annex. In order to obtain this information, the project proponent must select the route which provides the shortest travel time without traffic as the commuting route from the registered residential to the work address and the return trip. The travel time obtained from the commuting route must be compared with that from using public transportation, walking and biking (alternate transportation mode). Note that the query to Google Maps (or similar service) must be performed during typical member commute hours to obtain accurate and shorter travel times for the public transport modes. If the travel time using one of the alternate transportation modes is no more than 15 minutes compared to the commute using a car either to work or from work, *alternate transportation mode* is the mode of transportation in the baseline scenario for the member (see Section 6 above).

Where the CMMS is capable of querying services like Google Maps in real time during members' carpool trips, the CMMS may use the shortest in-traffic travel route as the SOBT route for the baseline scenario for the corresponding carpool trip. Note that the SOBT route is determined every time a carpool trip is made and may be different from time to time. This puts additional scalability requirement on CMMS and additional cost for the project proponent to subscribe to use some services. Results of such queries must be stored as part of the carpool trip data for review and data integrity checks.

Methodology for Pavement Application using Sulphur Substitute

Version 1.0

15 May 2015

Sectoral Scopes 4, 6 & 7

Methodology developed by:

Shell Malaysia Trading Sdn Bhd

In parternship with:

Cap-Op Energy Inc.

Viresco Solutions Inc.

Table of Contents

1 SOURCES

This methodology is based on the *Quantification Protocol for the Substitution of Bitumen Binder in Hot Mix Asphalt Production and Usage v1.0*, issued under the Alberta Specified Gas Emitters Regulation. The methodology uses the latest version of the following CDM tools:

- *Combined tool to identify the baseline scenario and demonstrate additionality*
- *Tool for the demonstration and assessment of additionality*

In addition, technical and good practice guidance was obtained from Environment Canada's annual greenhouse gas (GHG) reporting, the US Envirnmental Protection Agency's (EPA) Emission Inventory, the Intergovernmental Panel on Climate Change (IPCC), the Canadian Association of Petroleum Producers (CAPP) and various other reliable sources of information pertaining to the hot mix asphalt industry. The good practice guidance and scienctific literature used to develop the methodology are presented in Section 10.

2 SUMMARY DESCRIPTION OF THE METHODOLOGY

Additionality and Crediting Method	
Additionality	Project Method
Crediting Baseline	Project Method

This methodology quantifies the GHG emission reductions achieved by the substitution of a proportion of the bitumen binder used in conventional hot asphalt paving with a sulphur product. The use of a sulphur product in place of a portion of bitumen binder reduces required quantities of aggregate and bitumen, reduces fuel usage due to reduced mix production temperatures and reduces GHG emissions from the hot mix plant stack and paving.

The sulphur product being substituted for asphalt must be either sulphur extended asphalt modifier (SEAM) pellets or a similar solid sulphur modifier composed of sulphur and small quantities of plasticizer and H_2S scavenger additives. Other additives such as carbon black could be used to impart particular characteristics to the final product. The product may also contain wax additives, used to further reduce hot mix production and compaction temperatures. This methdology applies to hot mix facilities using either formulation of SEAM (with and without wax additives). This methodology is not applicable to project proponents substituting other products for asphalt binder in paving mix. The methodology applies to new construction and overlaying of existing roads. Inclusion of reclaimed asphalt pavement (RAP) would reduce the need for virgin asphalt, so it is possible to combine RAP and SEAM.

A project applying this methodology is considered to be the GHG emissions reductions achieved from the production of sulphur extended asphalt for use in the paving of one or more paving segments. Projects that are applying thismethodology may include hot mix production facilities that do not exclusively produce sulphur-modified asphalts. However, any conventional hot mix asphalt procuded during the crediting period is not eligible for inclusion with the project. (

The project proponent may be the technology owner, hot mix asphalt producer/manufacturer, road owner, or other party associated with the production of sulphur-extended asphalt or development of paving segments paved with sulphur-extended asphalt.

Given that the project proponent could any one of entities listed above, clear right of use must be demonstrated through contractual agreement, or otherwise, in order to to avoid the risk of double counting with other participants in the supply chain.

The project proponent must develop the baseline scenario appropriately for projects that include multiple project activity instances (ie, multiple paving segments), ensuring that the baseline selected is appropriate for all projects to be included in the aggregated quantification.

The baseline scenario would be the production and use of conventional hot mix asphalt, whose composition of aggregate versus bitumen binder will vary depending on the type of road paved (eg, highway versus city street). The project activity could be implemented at existing hot mix facilities or implemented at new facilities as a best practice technology.

Note that as emission reductions generated by projects that apply this methodology are attributed partly to indirect emission from electricity production, projects developed in jurisdictions that have cap-and-trade programs require assessment to ensure double counting does not occur. Therefore, project proponents should be aware of the VCS rules on double counting when a proposed project occurs in a jurisdiction with a cap and trade program covering the electrivity sector, which might render the project unviable.

3 DEFINITIONS

In addition to the definitions set out in VCS document *Program Definitions*, the following definitions apply to this methodology:

Additive
Materials or substances that are included in an asphalt product which do not serve to bind the aggregate, rather they facilitate or modify the binder (or binder substitute) properties to better meet production requirements or product specifications

Aggrerate
Coarse particulate material including sand, gravel, crushed stone, slag, and recycled concrete which may be sourced from gravel pits, quarries and other local areas surrounding the hot mix facility

Binder

A waterproof adhesive that binds the aggregate together. Conventional binder is comprised of bitumen, but for the purposes of this methodology, the word binder may refer to a mix of bitumen and binder substitute.

Binder Substitute

Materials that serve to displace bitumen (the primary conventional binder used for hot mix asphalt production). These substitutes help extend supplies of non-renewable fossil fuels and may also provide other benefits (molten sulphur is an example of a binder substitute which provides lower mix plant temps as a benefit). Binder substitute may be sulphur extender, or an equivalent product.

Bitumen

A viscous liquid petroleum-based product, produced from the heavy crude oil refining and distillation process. Bitumen is also known as asphalt in some parts of the world.

Bitumen Handling Emissions

Intentional and unintentional GHG emissions during bitumen production, handling and storage from the joints, seals and other components of processing, piping and treatment equipment

Conventional Hot Mix Aphalt

A common mixture of asphalt binder and coarse and fine aggregate delivered from the hot mix facility to the silo or truck for load-out and delivery to the paving site. The majority of roads are constructed with conventional hot mix asphalt and operating temperature varying by local project conditions.

Paving Segment

The surface (road, trail, parking lot or other type of surface), specifiable in geographic extent, that is paved with the materials produced from the project activity

Reclaimed Asphalt Pavement (**RAP**)

Asphalt that is produced from feedstocks recovered from existing paved surfaces. RAP can be applied in-situ or recycled through a hot mix facility where it is blended with conventional hot mix asphalt or with a mix including sulphur solid modifers.

Solid Sulphur

The solid state form of elemental sulphur, with the chemical furmula S_8. Solid sulphur is a by-product of industrial processes, such as the desulphurization of natural gas and other hydrocarbon resources. Stockpiles of excess sulphur exist in hydrocarbon-producing regions of the world. Solid sulphur is not SEAM.

Sulphur Extended Asphalt Modifier (**SEAM**)

A solid sulphur extender that is composed of minimum 98 percent sulphur and small quantities of plasticizer and H_2S scavenger additives. SEAM is also referred to as sulphur modifier.

4 APPLICABILITY CONDITIONS

This methodology is applicable to the production and use of hot mix asphalt using a sulphur extender in the asphalt paving process, where the following conditions are met:

1. The baseline scenario is the production and use of hot mix asphalt for paving, and where solid sulphur is not used for paving or as any part of the paving process.
2. Under the baseline scenario, sulphur used in the project to produce hot mix asphalt is a byproduct of other industrial processes and is not produced for use as an extender or modifier in the paving process.
3. Project activities can be undertaken at either a new facility (greenfield site) or existing facility (brownfield site).
4. A proportion of the bitumen binder used in conventional hot mix asphalt production has been substituted with SEAM. This methodology is not applicable to activities that use other binder substitute products that replace bitumen; however, additives which facilitate the substitution of bitumen with SEAM are acceptable.
5. Production procedures must ensure a safe and functionally equivalent product to hot mix asphalt. This requires adherence to procedures issued by the SEAM manufacturer for the handling and storage of solid sulphur, handling and use of the SEAM, construction specifications and mix design. These specifications include appropriate handling temperatures and mix production temperatures. Additionally, any mix produced at temperatures exceeding the maximum allowable mix temperatures specified by the sulphur exptender manufacturer must be safely disposed of.
6. Asphalt products must meet all applicable legal and technical requirements. In the absence of technical specifications for asphalt, the project proponent must demonstrate that asphalt produced under the project scenario provides the equivalent function to asphalt that would have been produced under the baseline scenario.
7. The proportion of RAP used in the project scenario is equivalent to or less than the proporption of RAP used in the baseline scenario. RAP must be mixed at a hot mix facility (not insitu).
8. For projects that consist of multiple project activity instance (ie, multiple paving segments), all of the hot mix asphalt used in the project must have been produced at the same facility.

5 PROJECT BOUNDARY

The project boundary encompases the hot mix facility where the sulphur extended asphalt is produced, as well as the production and processing of bitumen and its additives.

Sources, sinks and reservoirs (SSRs) included in the project and baseline quantification include those that are within the hot mix facility , as well as others that are related to the processing and production of bitumen, bitumen extender, and the associated additives. A generalized process flow diagram of a typical project and baseline are presented below in Figures 1 and 2, respectively.

Figure 1: Project Process Flow Diagram

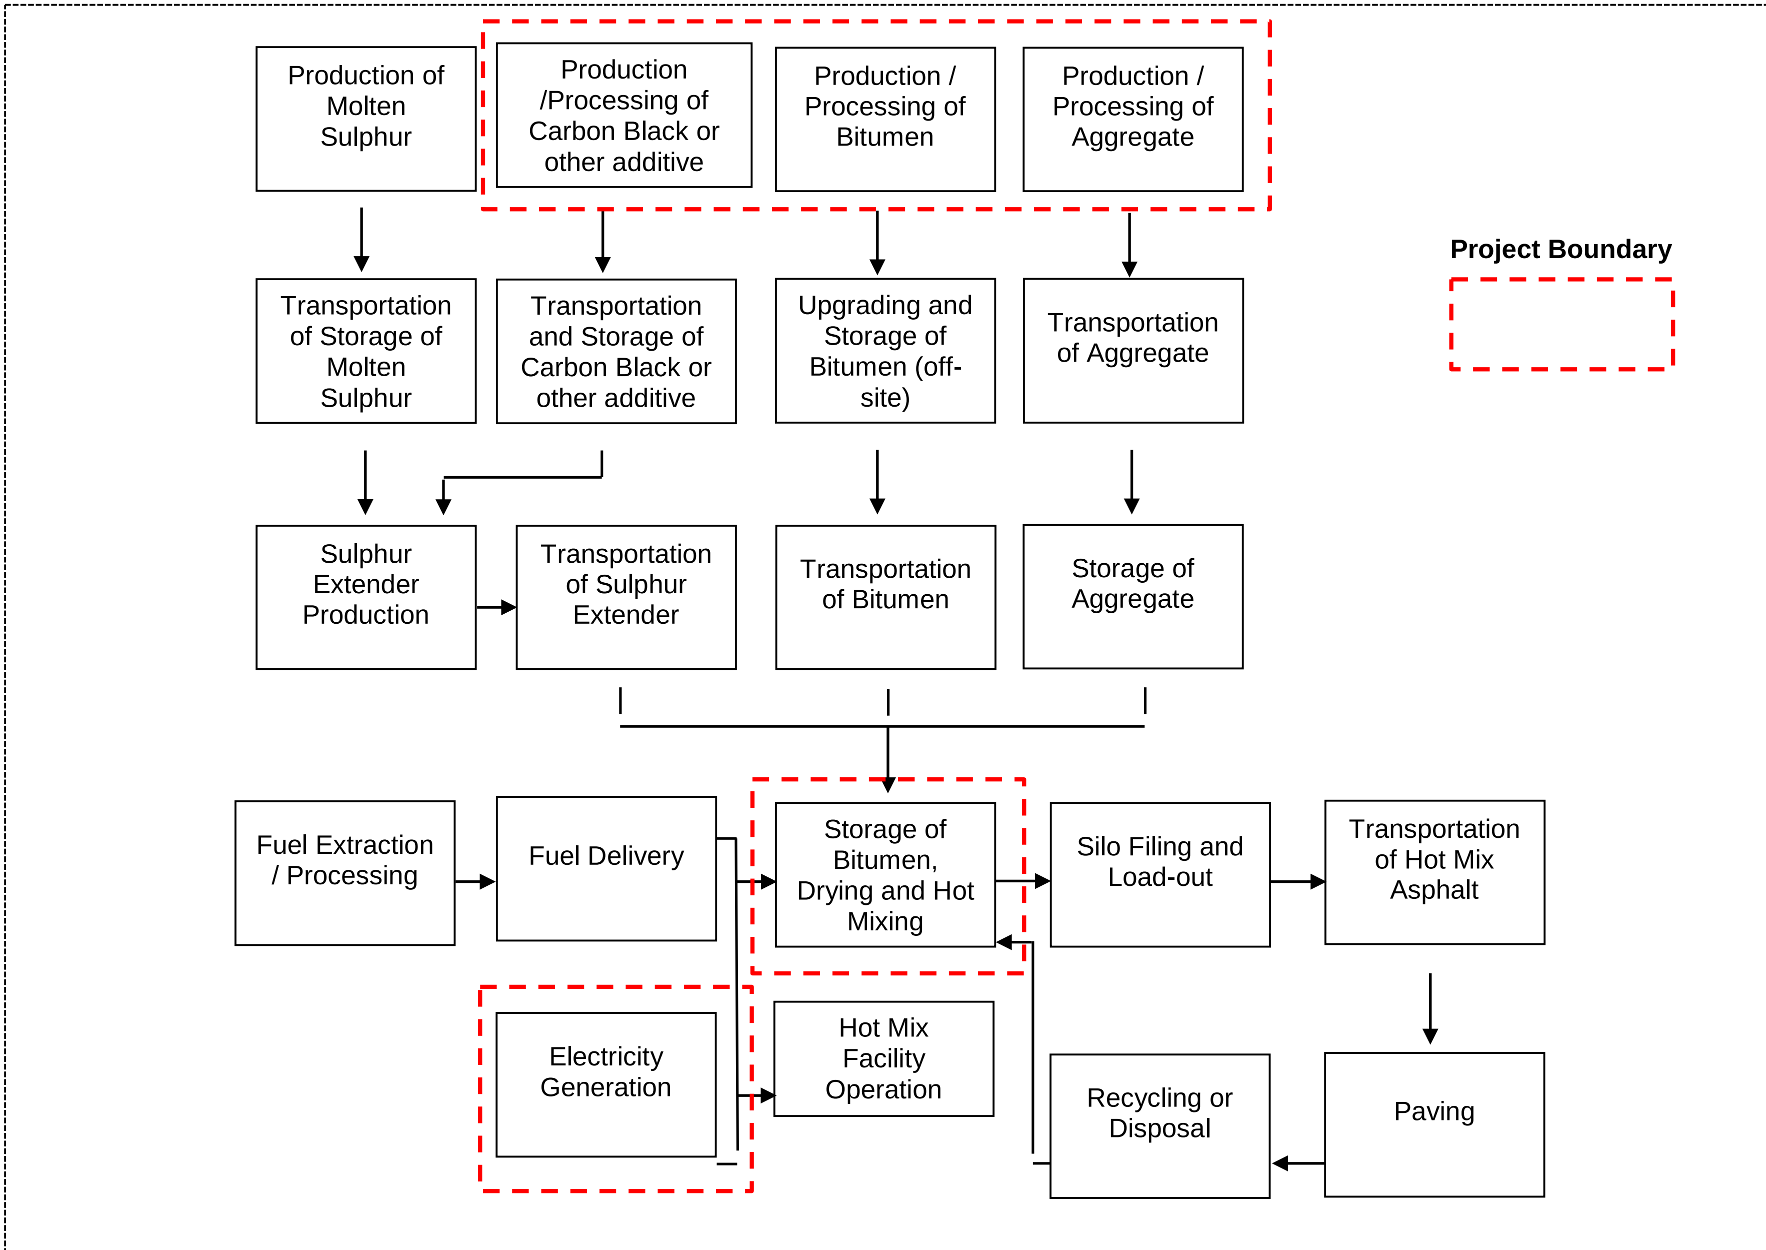

Figure 2: Baseline Process Flow Diagram

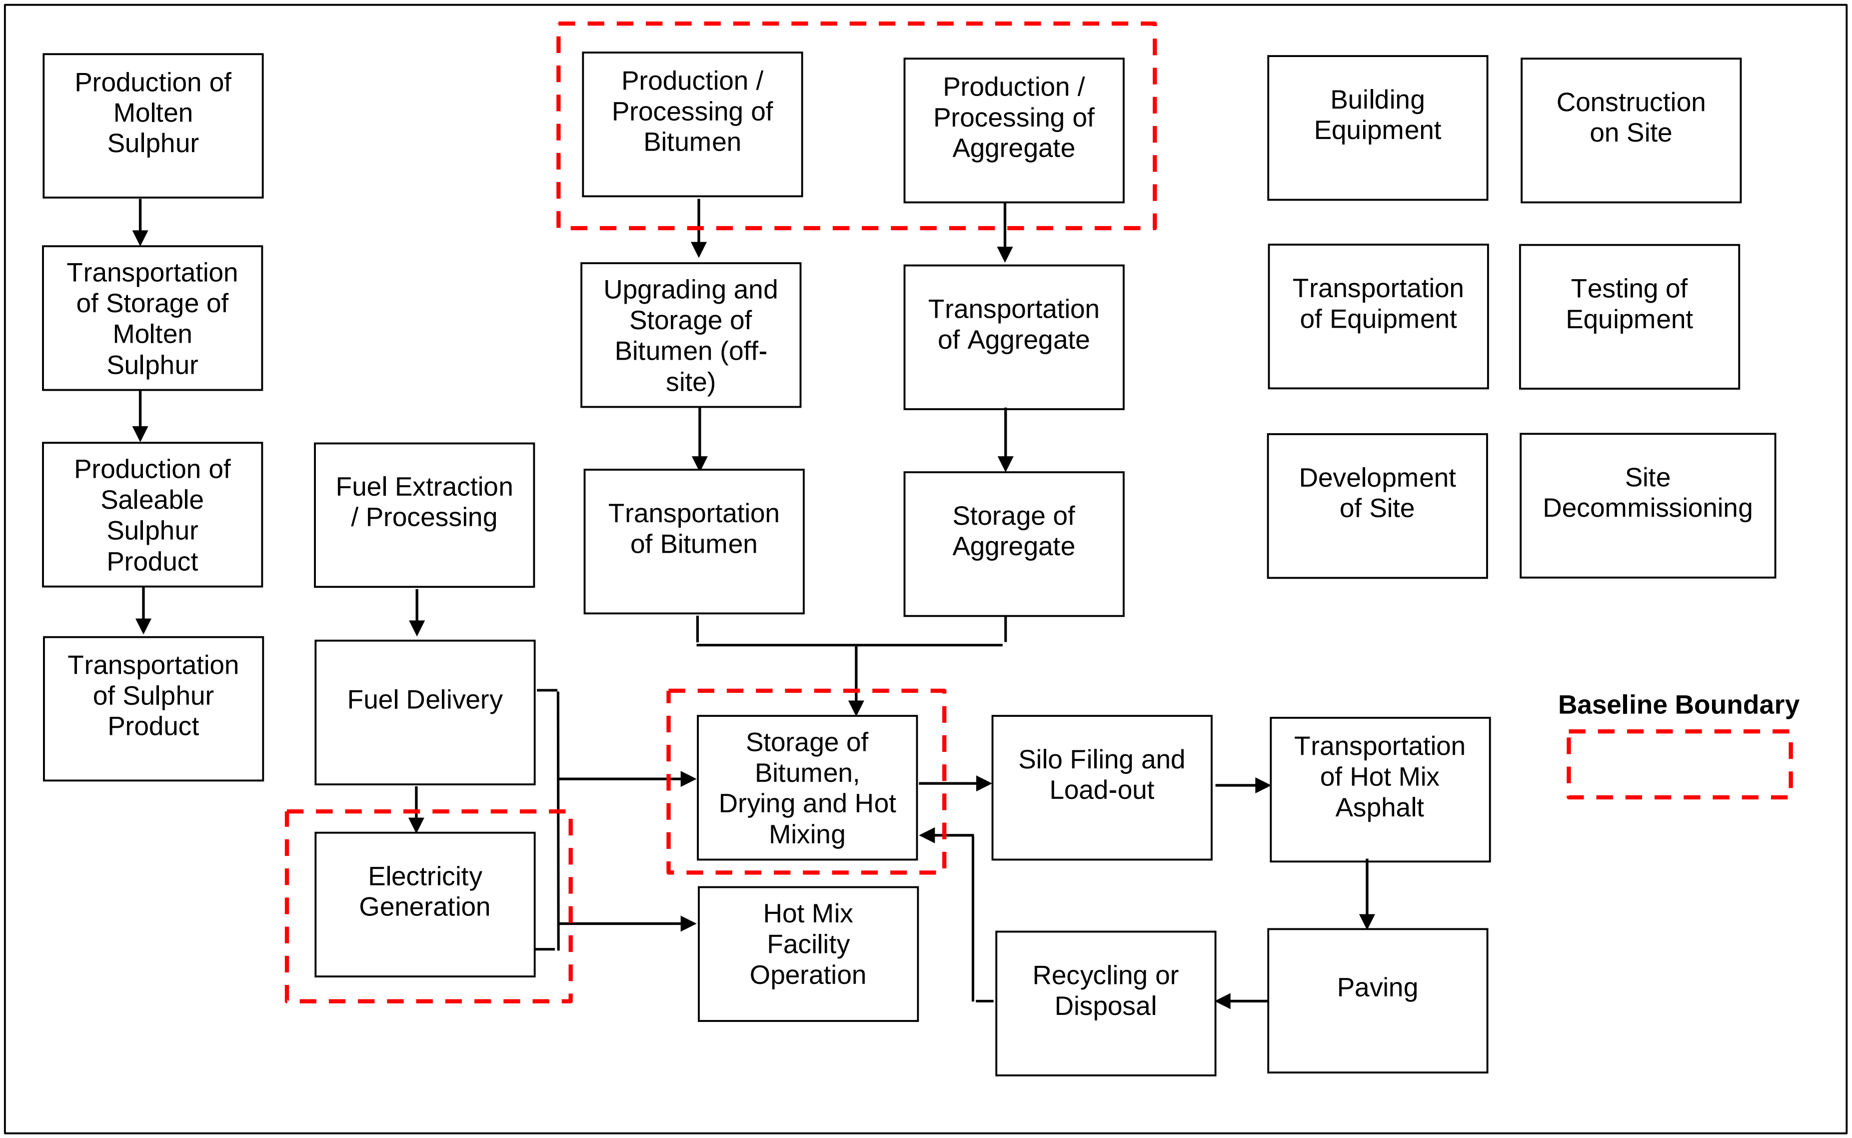

Table 1 below provides justification for the inclusion or exclusion of each of the potential SSRs in the project and baseline scenarios. The project proponent must justify the baseline and project SSRs selected for quantification in the project.

Table 1: GHG Sources, Sinks and Reservoirs

Source		Controlled, Related, or Affected	Gas*	Included	Justification/Explanation
Baseline	Production of molten sulphur	Related	CO_2	No	Excluded as the quantity of molten sulphur produced in the project and baseline scenarios are functionally equivalent. Sulphur is a by-product of gas processing and petroleum refining and would be produced in both the project and baseline scenarios in the same quantity.
			CH_4	No	
			N_2O	No	
	Production/ processing of bitumen	Related	CO_2	Yes	Emissions from the production/processing of bitumen used in asphalt production may be material and can be quantified.
			CH_4	Yes	
			N_2O	Yes	
	Production/Processing of Aggregate	Related	CO_2	Yes	Emissions from the production/processing of aggregate used in asphalt production may be material and may be quantified.
			CH_4	Yes	
			N_2O	Yes	
	Transportation and storage of molten sulphur	Related	CO_2	No	Emissions are based on the quantity of sulphur used in the project scenario, therefore an equivalent quantity of sulphur would be transported in both the project and baseline scenarios. The emissions under this SSR will be functionally equivalent in the project and baseline, as the emissions resulting from transporting the sulphur to the hot mix facility compared to the baseline storage location are negligible.
			CH_4	No	
			N_2O	No	
	Upgrading and storage of bitumen (off-site)	Related	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario. This applies to fuel usage and fugitive emissions attributed to this SSR.
			CH_4	No	
			N_2O	No	

	Transportation of aggregate	Related	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario.
			CH_4	No	
			N_2O	No	
	Production of saleable sulphur product	Related	CO_2	No	Emissions are based on the quantity of sulphur used in the project scenario, therefore an equivalent quantity of sulphur would be produced in both the project and baseline scenarios. The emissions under this SSR will be functionally equivalent in the project and baseline, as the production by sulphur processing facilities will remain the same.
			CH_4	No	
			N_2O	No	
	Transportation of sulphur product	Related	CO_2	No	Excluded as the emissions from transportation are negligible.
			CH_4	No	
			N_2O	No	
	Transportation of Bitumen	Related	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario.
			CH_4	No	
			N_2O	No	
	Fuel Extraction/Processing	Related	CO_2	No	Excluded for conservativeness to ensure emission reductions from indirect emission sources are not credited to the project
			CH_4	No	
			N_2O	No	
	Transportation of Bitumen	Related	CO_2	No	Excluded for conservativeness to ensure emission reductions from indirect emission sources are not credited to the project
			CH_4	No	
			N_2O	No	
	Fuel delivery	Related	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario.
			CH_4	No	
			N_2O	No	
	Electricity generation	Related	CO_2	Yes	Indirect emissions from electricity use may be a material source of emissions. The project proponent must include electricity in the methodology if it is demonstrated to be conservative.
			CH_4	Yes	
			N_2O	Yes	
	Storage of aggregate	Controlled	CO_2	No	Excluded for simplification. This is conservative as the emissions are
			CH_4	No	

			N_2O	No	higher under the baseline scenario.
	Storage of bitumen, drying and hot mixing	Controlled	CO_2	Yes	Included as the emissions may be material and may be quantified. Emissions are dependent on the hot mix temperatures and will therefore vary between the baseline and project scenarios. N_2O emissions are relevant for fuel combustion emissions quantified in this SSR.
			CH_4	Yes	
			N_2O	Yes	
	Hot mix facility operation	Controlled	CO_2	No	Excluded as the hot mix facility's operations will not be impacted by the project activity and will therefore be functionally equivalent in the project and baseline scenarios.
			CH_4	No	
			N_2O	No	
	Silo filling and load-out	Controlled	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario.
			CH_4	No	
			N_2O	No	
	Transportation of hot mix asphalt	Related	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario.
			CH_4	No	
			N_2O	No	
	Paving	Controlled	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario.
			CH_4	No	
			N_2O	No	
	Recycling or disposal	Related	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario.
			CH_4	No	
			N_2O	No	
	Building equipment	Related	CO_2	No	Emissions from building equipment are not material given the long project life, and the minimal building equipment typically required.
			CH_4	No	
			N_2O	No	
	Transportation of equipment	Related	CO_2	No	Emissions from transportation of equipment are not material given the long project life, and the minimal transportation of equipment typically required.
			CH_4	No	
			N_2O	No	
	Development of site	Related	CO_2	No	Emissions from development of site are not material given the long project
			CH_4	No	

			N_2O	No	life, and the minimal development of site typically required.
	Construction of site	Related	CO_2	No	Emissions from construction of site are not material given the long project life, and the minimal construction of site typically required.
			CH_4	No	
			N_2O	No	
	Testing of equipment	Related	CO_2	No	Emissions from testing of equipment are not material given the long project life, and the minimal testing of equipment typically required.
			CH_4	No	
			N_2O	No	
	Site decommissioning	Related	CO_2	No	Emissions from decommissioning are not material given the long project life, and the minimal decommissioning typically required.
			CH_4	No	
			N_2O	No	
Project	Production of molten sulphur	Related	CO_2	No	Excluded as the quantity of molten sulphur produced in the project and baseline scenarios are functionally equivalent. Sulphur is a by-product of gas processing and would be produced in both the project and baseline scenarios in the same quantity.
			CH_4	No	
			N_2O	No	
	Production/processing of carbon black or other additives	Related	CO_2	Yes	Emissions from the production of additives used in the sulphur extender product may be material and may be quantified.
			CH_4	Yes	
			N_2O	No	Emissions are negligible.
	Production/ processing of bitumen	Related	CO_2	Yes	Emissions from the production/processing of bitumen used in asphalt production may be material and may be quantified.
			CH_4	Yes	
			N_2O	Yes	
	Production/processing of aggregate	Related	CO_2	Yes	Emissions from the production/processing of aggregate used in asphalt production may be material and may be quantified.
			CH_4	Yes	
			N_2O	Yes	
	Transportation and storage of molten sulphur	Related	CO_2	No	Emissions are based on the quantity of sulphur used in the project scenario, therefore an equivalent quantity of sulphur would be transported in both the project and baseline scenarios.
			CH_4	No	
			N_2O	No	

					The emissions under this SSR will be functionally equivalent in the project and baseline, as the emissions resulting from transporting the sulphur to the hot mix facility compared to the baseline storage location are negligible.
	Transportation and storage of carbon black or other additives	Related	CO_2	No	Excluded as the emissions are negligible given the small quantities of additive consumed.
			CH_4	No	
			N_2O	No	
	Upgrading and storage of bitumen (off-site)	Related	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario. This applies to fuel usage and fugitive emissions attributed to this SSR.
			CH_4	No	
			N_2O	No	
	Transportation of aggregate	Related	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario.
			CH_4	No	
			N_2O	No	
	Sulphur extender production	Related	CO_2	No	Excluded for simplification. Since the emissions are based on the quantity of sulphur extender used, the emissions would be functionally equivalent under the baseline and project scenarios. The production process includes mixing and solidification of elemental sulphur which occurs in the baseline, therefore emissions are considered to be equivalent between project and baseline.
			CH_4	No	
			N_2O	No	
	Transportation of sulphur extender	Related	CO_2	No	Excluded as the emissions from transportation are negligible.
			CH_4	No	
			N_2O	No	
	Transportation of Bitumen	Related	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario.
			CH_4	No	
			N_2O	No	
	Fuel Extraction/Proces	Related	CO_2	No	Excluded for conservativeness to ensure emission reductions from
			CH_4	No	

	sing		N_2O	No	indirect emission sources are not credited to the project
	Fuel Delivery	Related	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario.
			CH_4	No	
			N_2O	No	
	Electricity generation	Related	CO_2	Yes	Indirect emissions from electricity use may be a material source of emissions. The project proponent must include electricity in the methodology if it is demonstrated to be conservative.
			CH_4	Yes	
			N_2O	Yes	
	Storage of aggregate	Controlled	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario.
			CH_4	No	
			N_2O	No	
	Storage of bitumen, drying and hot mixing	Controlled	CO_2	Yes	Included as the emissions may be material and may be quantified. Emissions are dependent on the hot mix temperatures and will therefore vary between the baseline and project scenarios. N_2O emissions are relevant for fuel combustion emissions quantified in this SSR.
			CH_4	Yes	
			N_2O	Yes	
	Hot mix facility operation	Controlled	CO_2	No	Excluded as the hot mix facility's operations will not be impacted by the project activity and will therefore be functionally equivalent in the project and baseline scenarios.
			CH_4	No	
			N_2O	No	
	Silo filling and load-out	Controlled	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario.
			CH_4	No	
			N_2O	No	
	Transportation of hot mix asphalt	Related	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario.
			CH_4	No	
			N_2O	No	
	Paving	Controlled	CO_2	No	Excluded for simplification. This is conservative as the emissions are higher under the baseline scenario.
			CH_4	No	
			N_2O	No	
	Recycling or disposal	Related	CO_2	No	Excluded for simplification. This is conservative as the emissions are
			CH_4	No	

			N_2O	No	higher under the baseline scenario.

*Gas types listed are those that are relevant at least once to the project or baseline scenario. No refrigerants are relevant to this methodology.

The temporal project boundary includes the operation of a new or existing hot mix facility during the incorporation of a sulphur extender project. SSRs related to the construction and decommissioning of the hot mix facility are considered outside the scope of this methodology and have been excluded from quantification. This is reasonable given the minimal emissions associated with the construction and decommissioning phases and the long operational life of hot mix facilities.

6 PROCEDURE FOR DETERMINING THE BASELINE SCENARIO

The baseline scenario for projects applying this methodology is the production of conventional hot mix asphalt. The project proponent must demonstrate that this is the most plausible baseline for the project using the most recent version of the CDM *Combined tool to identify the baseline scenario and demonstrate additionality*. The project proponent must use the tool to identify all realistic and credible baseline alternatives, to identify barriers and to assess which alternatives are prevented by these barriers. In doing so, relevant local regulations governing the use of different technologies and technical specifications of concrete products must be taken into account.

Baseline scenarios that include RAP may be considered if the baseline scenario is one with an equivalent or lower proportion of RAP. The project proponent must demonstrate that the use of sulphur extender displaces conventional hot mix bitumen in the baseline scenario. The quantification methods provided in this document do not account for sulphur displacing RAP. Projects using RAP may adjust the volumes or proportions of bitumen displacement with justification, based on the results of the baseline analysis, to ensure a conservative assertion.

7 PROCEDURE FOR DEMONSTRATING ADDITIONALITY

Additionality must be assessed and demonstrated using the most recent version of the CDM *Combined tool to identify the baseline scenario and demonstrate additionality* or the CDM *Tool for the demonstration and assessment of additionality*.

8 QUANTIFICATION OF GHG EMISSION REDUCTIONS AND REMOVALS

8.1 Baseline Emissions

Emissions under the baseline scenario (in tonnes CO_2e) are determined using the following equation:

$$BE_y = \frac{(BE_{Bitumen} + BE_{Aggregate} + BE_{Production} + BE_{Electricity})}{1000} \quad (1)$$

Where:

BE_y = Baseline emissions in a given year y (t CO_2e)

$BE_{Bitumen}$ = Emissions due to the production and processing of bitumen (kg CO_2e)

$BE_{Aggregate}$ = Emissions due to the production and processing of aggregate (kg CO_2e)

$BE_{Production}$ = Emissions due to the storage of bitumen, drying and hot-mixing (k CO_2e)

$BE_{Electricity}$ = Emissions due to the generation of electricity for operating the hot mix facility (kg CO_2e)

The emissions due to the production and processing of bitumen are calculated as follows:

$$BE_{Bitumen} = \sum_x \left(MF_{Bitumen\ B} \times Mass_{Paving} \times EF\ Bit\ Production_x \times GWP_x\right) \quad (2)$$

Where:

$BE_{Bitumen}$ = Emissions due to the production and processing of bitumen (kg CO_2e)

$MF_{Bitumen\ B}$ = Mass fraction of bitumen consumed (kg / t of hot mix produced)

$Mass_{Paving}$ = Mass of hot mix asphalt produced (t)

$EF\ Bit\ Production_x$ = Emissions factor for bitumen production and processing for each GHG listed (kg GHG / kg bitumen)

GWP_x = Global warming potential for each GHG

x = Value for each GHG

The emissions due to the production and processing of aggregate are calculated as follows:

$$BE_{Aggregate} = \sum_x \left(MF_{Aggregate\ B} \times Mass_{Paving} \times EF\ Aggregate_x \times GWP_x\right) \quad (3)$$

Where:

$BE_{Aggregate}$ = Emissions due to the production and processing of aggregate (kg CO_2e)

$MF_{Aggregate\ B}$ = Mass fraction of aggregate consumed (kg / t of hot mix produced)

$Mass_{Paving}$ = Mass of hot mix asphalt produced (t)

$EF\ Aggregate_x$ = Emissions factor for aggregate production and processing for each GHG listed (kg GHG / kg aggregate)

GWP_x = Global warming potential for each GHG

x = Value for each GHG

The emissions due to the storage of bitumen, drying and hot mixing are calculated using the following equations.

$$BE_{Production} = BE_{Hot\ mix\ stack} + BE_{Fuel\ usage} \quad (4)$$

Where:

$BE_{Production}$ = Emissions due to the storage of bitumen, drying and hot-mixing (kg CO_2e)

$BE_{Hot\ mix\ stack}$ = Emissions from hot mix stack (kg CO_2e)

$BE_{Fuel\ usage}$ = Emissions from fuel usage (kg CO_2e)

The emissions from the hot mix stack are calculated as follows:

$$BE_{Hot\ mix\ stack} = MF_{BitumenB} \times Mass_{Paving} \times EF\ Mixer_{CH4} \times GWP_{CH4} \quad (5)$$

Where:

$BE_{Hot\ mix\ stack}$ = Emissions from hot mix stack (kg CO_2e)

$MF_{Bitumen\ B}$ = Mass fraction of bitumen consumed (kg / t of hot mix produced)

$Mass_{Paving}$ = Mass of hot mix asphalt produced (t)

$EF\ Mixer_{CH4}$ = Emissions factor for CH4 during mixing (kg CH4 / kg bitumen)

GWP_{CH4} = Global warming potential CH4

The emissions due to fuel usage during hot mixing are calculated as follows:

$$BE_{fuel\ usage} = \sum_{i,x} \left(Mass_{Paving} \times Vol\ Fuel\ Mixing_{i,B} \times EF\ Fuel_{i,x} \times GWP_x \right) \quad (6)$$

Where:

$BE_{fuel\ usage}$ = Emissions from fuel usage (kg CO_2e)

$Mass_{Paving}$ = Mass of hot mix asphalt produced (t)

$Vol\ Fuel\ Mixing_{i,\ B}$ = Volume of each type of fuel combusted (L, m3 or other / t of asphalt produced)

$EF\ Fuel_{i,\ x}$ = Emissions factor for fuel combustion (kg GHG / L, m3 or other)

x = Value for each GHG

i = Value for each fuel type applicable to project

The volumes of each type of fuel combusted during hot mixing are calculated based on the heating requirements for hot mixing and the theoretical volume of fuel needed to produce this heat, using the following equations:

$$Vol\ Fuel\ Mixing_i = Vol\ Fuel\ Mixing_{i\ Aggregate} + Vol\ Fuel\ Mixing_{i\ Bitumen} \quad (7)$$

$$Vol\ Fuel\ Mixing_{i\ Aggregate} = \frac{MF_{Aggregate,B} \times Mass_{Paving} \times C_{Aggregate} \times \left(T_{Hot\ mix} - T_{Aggregate}\right)}{HV_{Fuel\ i} \times Eff} + MF_{Aggregate,B} \times Mass_{Paving} \times Vol\ Fuel_{agg\ i} \quad (8)$$

$$Vol\ Fuel\ Mixing_{i\ Bitumen} = \frac{MF_{Bitumen,B} \times Mass_{Paving} \times\ C_{Bitumen} \times (T_{Hot\ mix} -\ T_{Bitumen})}{HV_{Fuel\ i} \times Eff} \quad (9)$$

Where:

Vol Fuel Mixing$_i$	=	Emissions from fuel usage (kg CO_2e)
Vol Fuel Mixing$_{i\ Aggregate}$	=	Mass of hot mix asphalt produced (t)
Vol Fuel Mixing$_{i\ Bitumen}$	=	Volume of each type of fuel combusted (L, m3 or other / t of asphalt produced)
EF Fuel$_{i,\ x}$	=	Emissions factor for fuel combustion (kg GHG / L, m3 or other)
x	=	Value for each GHG
i	=	Value for each fuel type applicable to project
MF$_{Aggregate,B}$	=	Mass fraction of aggregate consumed (kg / t of hot mix produced)
MF$_{Bitumen,\ B}$	=	Mass fraction of bitumen consumed (kg / t of hot mix produced)
Mass$_{Paving}$	=	Mass of hot mix asphalt produced (t)
C$_{Aggregate}$	=	Specific heat capacity of aggregate (kJ / kg °C)
C$_{Bitumen}$	=	Specific heat capacity of bitumen (kJ / kg °C)
T$_{Hotmix}$	=	Temperature of hot mix asphalt production (°C)
T$_{Aggregate}$	=	Temperature of aggregate (°C)
T$_{Bitumen}$	=	Temperature of bitumen (°C)
HV$_{Fuel\ i}$	=	Heating value of fuel consumed (kJ / m^3)
Eff	=	Fuel combustion and burner efficiency (%).
Vol Fuel$_{agg\ i}$	=	Volume of fuel combusted for aggregate drying (L, m^3 or other / kg of aggregate)

For projects where site-specific stack emissions sampling data is available, the project proponent must calculate emissions due to the storage of bitumen, drying and hot mixing under the baseline scenario as follows:

$$BE_{Hot\ mix\ stack} = \left(\frac{Mass_{Paving} \times EF\ Mixer_{CH4,B,SS}}{Rate_B}\right) GWP_{CH4} + \frac{Mass_{Paving} \times EF\ Mixer_{CO2,B,SS}}{Rate_B} \quad (10)$$

Where:

Mass$_{Paving}$	=	Mass of hot mix asphalt produced (tonne)

EF $Mixer_{CH4, B, SS}$	=	Site-specific mass emission rate of CH_4 from the hot mix stack (kg / hr) during conventional hot mix production
EF $Mixer_{CO2, B,SS}$	=	Site-specific mass emission rate of CO_2 from the hot mix stack (kg / hr) during conventional hot mix production
$Rate_B$	=	Production rate of conventional hot mix asphalt during stack sampling period (tonne per hour)
GWP_{CH4}	=	Global warming potential for CH_4

The emissions due to electricity generation for operating hot mix facility are calculated as follows:

$$BE_{Electricity} = Electricity_{B} \times EF_{Elec} \quad (11)$$

Where:

$Electricity_{B}$	=	Electricity used in operating the hot mix facility in the baseline (kWh)
EF_{Elec}	=	Emissions factor for electricity (kg CO_2e/kWh)

8.2 Project Emissions

Emissions under the project scenario (in tonnes CO_2e) are determined using the following equation:

$$PE_y = \frac{(PE_{Add} + PE_{Bitumen} + PE_{Aggregate} + PE_{Production} + PE_{Electricity})}{1000} \quad (12)$$

Where:

PE_y	=	Project emissions in a given year, y (tonne CO_2e)
PE_{Add}	=	Emissions due to the production and processing of carbon black or other additives used in hot mix production (kg CO_2e)
$PE_{Bitumen}$	=	Emissions due to the production and processing of bitumen (kg CO_2e)
$PE_{Aggregate}$	=	Emissions due to the production and processing of aggregate (kg CO_2e)
$PE_{Production}$	=	Emissions due to the storage of bitumen, drying and hot-mixing (kg CO_2e)
$PE_{Electricity}$	=	Emissions due to the generation of electricity for operating the hot mix facility (kg CO_2e)

The emissions due to the production and processing of carbon black or other additives used under the project scenario must be quantified, the following equation provides guidance:

$$PE_{add} = \frac{Mass_{SE} \times \%CB \times EF\ Production_{CO2}}{100} + \frac{Mass_{SE} \times \%CB \times EF\ Production_{CH4}}{100} GWP_{CH4} \quad (13)$$

Where:

PE_{Add}	=	Emissions due to the production and processing of carbon black or other additives used in hot mix production (kg CO_2e)

$Mass_{SE}$	=	Mass of sulphur extender consumed (kg)
%CB	=	Percent of additive (ie. carbon black) in the sulphur extender used (%)
EF $Production_{CO2}$	=	CO_2 emissions factor for additive production (kg CO_2 /kg additive)
EF $Production_{CH4}$	=	CH_4 emissions factor for additive production (kg CH_4/kg additive)
GWP_{CH4}	=	Global warming potential for CH_4

The emissions due to the production and processing of bitumen are calculated as follows:

$$PE_{Bitumen} = \sum_{x}(Mass_{Bitumen} \times EF\ Bit\ Production_{x} \times GWP_{x}) \tag{14}$$

Where:

$PE_{Bitumen}$	=	Emissions due to the production and processing of bitumen (kg CO_2e)
$Mass_{Bitumen}$	=	Mass of bitumen consumed (kg)
EF Bit $Production_x$	=	Emissions factor for bitumen production and processing for each GHG listed (kg GHG/kg bitumen).
GWP_x	=	Global warming potential for each GHG (CO_2, CH_4 and N_2O)
x	=	Value for each GHG (CO_2, CH_4 and N_2O)

The emissions due to the production and processing of aggregate are calculated as follows:

$$PE_{Aggregate} = \sum_{x}\left(Mass_{Aggregate} \times EF\ Aggregate_{x} \times GWP_{x}\right) \tag{15}$$

Where:

$PE_{Aggregate}$	=	Emissions due to the production and processing of aggregate (kg CO_2e)
$Mass_{Aggregate}$	=	Mass of aggregate consumed (kg)
EF $Aggregate_x$	=	Emissions factor for aggregate production and processing for each GHG listed (kg GHG/kg of aggregate).
GWP_x	=	Global warming potential for each GHG (CO_2, CH_4 and N_2O)
x	=	Value for each GHG (CO_2, CH_4 and N_2O)

The emissions due to the storage of bitumen, drying and hot mixing are calculated as follows:

$$PE_{Production} = PE_{Hot\ mix\ stack} + PE_{Fuel\ usage} \tag{16}$$

Where:

$PE_{Production}$	=	Emissions due to the storage of bitumen, drying and hot-mixing (kg CO_2e)

$PE_{Hot\ mix\ stack}$ = Emissions from hot mix stack (kg CO2e)

$PE_{Fuel\ usage}$ = Emissions from fuel usage (kg CO2e)

The emissions from the hot mix stack are calculated as follows:

$$PE_{Hot\ mix\ stack} = Mass_{Bitumen} \times EF\ Mixer_{CH4} \times GWP_{CH4} \tag{17}$$

Where:

$PE_{Hot\ mix\ stack}$ = Emissions from hot mix stack (kg CO2e)

$Mass_{Bitumen}$ = Mass of bitumen consumed (kg)

$EF\ Mixer_{CH4}$ = CH_4 emissions factor for bitumen used in asphalt production (kg CH_4 / kg bitumen).

GWP_{CH4} = Global warming potential for CH_4

The emissions due to fuel usage during hot mixing are calculated as follows:

$$PE_{Fuel\ usage} = \sum_{i,x} \left(Vol\ Fuel\ Mixing_i \times EF\ Fuel_{i,x} \times GWP_x \right) \tag{18}$$

Where:

$PE_{Fuel\ usage}$ = Emissions from fuel usage (kg CO2e)

$Vol\ Fuel\ Mixing_i$ = Volume of each type of fuel combusted during hot mixing (L, m3 or other)

$EF\ Fuel_{i,x}$ = Emissions factor for fuel combustion for each type of fuel used and GHG listed (kg GHG / L, m^3 or other).

GWP_x = Global warming potential for each GHG (CO_2, CH_4 and N_2O)

x = Value for each GHG (CO_2, CH_4 and N_2O)

i = Value for each fuel type applicable to a project

For projects where site-specific stack emissions sampling data are available, the project proponent may calculate emissions due to the storage of bitumen, drying and hot mixing under the project scenario as follows:

$$PE_{Hot\ mix\ stack} = \frac{Mass_{Paving} \times EF\ Mixer_{CH4,SS} \times GWP_{CH4}}{Rate} + \frac{Mass_{Paving} \times EF\ Mixer_{CO2,SS}}{Rate} \tag{19}$$

Were:

$Mass_{Paving}$ = Mass of hot mix asphalt produced (tonne)

$EF\ Mixer_{CH4,\ SS}$ = Site-specific mass emission rate of CH_4 from the hot mix stack (kg/hr)

$EF\ Mixer_{CO2,\ SS}$ = Site-specific mass emission rate of CO_2 from the hot mix stack (kg/hr)

Rate = Production rate of hot mix asphalt during stack sampling period (tonne per hour)

GWP_{CH4} = Global warming potential for CH_4

The emissions due to electricity generation for operating hot mix facility are calculated as follows:

$$PE_{Electricity} = Electricity_P \times EF_{Elec} \tag{20}$$

Where:

$Electricity_P$ = Electricity used in operating the hot mix facility in the project (kWh)

EF_{Elec} = Emissions factor for electricity (kg CO_2e/kWh)

8.3 Leakage

There are no known sources of leakage for this project activity.

8.4 Summary of GHG Emission Reduction and/or Removals

The emission reductions for this project activity are calculated as follows:

$$ER_y = BE_y - PE_y \tag{21}$$

Where:

ER_Y = Net GHG emission reductions and/or removals in year y

BE_Y = Baseline emissions in year y

PE_y = Project emissions in year y

9 MONITORING

9.1 Data and Parameters Available at Validation

The following data must be made available at validation by the project proponent. Default values may vary according to the physical location of the project activity. The project proponent must provide evidence and justification that the values presented here are applicable to the project, or provide and justify project-specific values as needed.

Should the data parameters listed below not be available at the time of validation, the project proponent must provide a plan for determining and/or monitoring the data during the project. All parameters used must be reviewed at each verification period to ensure the most current and conservative value is used in calculations.

Data / Parameter	$C_{Bitumen}$
Data unit	kJ / kg C°
Description:	Specific heat capacity of bitumen
Equations	9
Source of data	Value of physical or chemical property
Value applied	2.093 kJ / kg C°

Justification of choice of data or description of measurement methods and procedures applied	Based on thermodynamic principles and the theoretical heat capacity of bitumen.
Purpose of data	Calculation of baseline emissions
Comments	The project proponent must determine if the bitumen used for the project is consistent with the definition provided in Section 3.0.

Data / Parameter	$C_{Aggregate}$
Data unit	kJ / kg C°
Description	Specific heat capacity of aggregate
Equations	8
Source of data	Value of physical or chemical property
Value applied	0.837 kJ/kg C°
Justification of choice of data or description of measurement methods and procedures applied	Based on thermodynamic principles and the theoretical heat capacity of aggregate.
Purpose of data	Calculation of baseline emissions
Comment	The project proponent must determine if the aggregate used for the project is consistent with the definition provided in Section 3

Data / Parameter	$EF_{Aggregate}$
Data unit	kg GHG/kg of aggregate
Description	Emission factors for aggregate production
Equations	3, 15
Source of data	Estimation; the emission factor must be obtained or calculated from relevant industry data according to the most conservative and regionally appropriate approach possible.
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	The emissions intensity of aggregate production may vary depending on the type and source of the aggregate used. National emissions factors, or emissions factors created by local industry using internationally accepted procedures should be used preferentially. Regional emissions factors

	may be used if National or local emissions factors are unavailable. International emissions factors may be used if regional emissions factors are unavailable. In the absence of an appropriate emission factor, a zero value may be assumed. This is conservative as aggregate consumption is higher in the baseline scenario.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	$EF_{Bit\ Production}$
Data unit	kg GHG / kg Bitumen
Description	Emission factors for bitumen production
Equations	14
Source of data	Estimation; the emission factor must be obtained or calculated from relevant industry data according to the most conservative and regionally appropriate approach possible.
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	National emissions factors, or emissions factors created by local industry using internationally accepted procedures should be used preferentially. Regional emissions factors may be used if national or local emissions factors are unavailable. International emissions factors may be used if regional emissions factors are unavailable. In the absence of any default value, the reference values provided by CAPP (Appendix A, Table A1) may be used.
Purpose of data	Calculation of project emissions
Comment	The project proponent must ensure that the default value is representative of the type and composition of bitumen used in the project. Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	$EF_{MixerCH4}$
Data unit	kg CH_4/kg bitumen
Description	Methane emission factor for bitumen use in hot mixing
Equations	
Source of data	Estimation; the emission factor must be obtained or calculated from relevant industry data according to the most conservative and regionally appropriate approach possible.
Value applied	5 and 17
Justification of choice of data or description of measurement methods and procedures applied	Emission factors are available from equipment manufacturers or governing authorities. National emissions factors, or emissions factors created by local industry using internationally accepted procedures should be used preferentially. Regional emissions factors may be used if national or local emissions factors are unavailable. International emissions factors may be used if regional emissions factors are unavailable. In the absence of manufacturer-specific emission factors, the emission factors listed in Appendix A, Table A2 must be used
Purpose of data	Calulcation of baseline emissions Calculation of project emissions
Comment	The project proponent must ensure that the default value is representative of the type and composition of product used in the project. Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	EF_{Fuel}
Data unit	kg GHG (CO_2, CH_4, N_2O) per L, m3 or other of each type of fuel used
Description	Emission factors for fuel combustion
Equations	6, 9 and 18
Source of data	Estimation; the emission factor must be obtained or calculated from relevant industry data according to the most conservative and regionally appropriate approach

	possible.In the absence of local or regional data, reference values must be obtained from the most recent version of the IPCC guidelines for National Greenhouse Gas Inventories.
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	National emissions factors, or emissions factors created by local industry using internationally accepted procedures should be used preferentially. Regional emissions factors may be used if national or local emissions factors are unavailable. International emissions factors may be used if regional emissions factors are unavailable.In the absence of local or regional data, reference values must be obtained from the most recent version of the IPCC guidelines for National Greenhouse Gas Inventories
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	The project proponent must ensure that the default value is representative of the type and composition of product used in the project. Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics.This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	$T_{hot\ mix}$
Data unit	Degree Celsius
Description	Temperature of hot mix asphalt production
Equations	9
Source of data	Estimation based on product requirements, site specific technical analysis or measurement
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Default values from industry common practice or from applicable road construction standards must be used when available. Or, it may be measured at the hot mix facility prior to the use of sulphur extender.
Purpose of data	Calculation of baseline emissions
Comment	Default value is 144 deg C based on asphalt production in

	Canada. A temperature of 142 deg C may be more appropriate for softer asphalt or low-volume highways. The project proponent must ensure that the default value is representative of the type and composition of product used in the project. Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics. This parameter may be updated over the course of the crediting period (as project description deviation) due to the availability of more recent information. For paving segement developers, a method may be specified to determine a parameter for aggregation of multiple paving segments rather than specifying a value for all paving segments included in the aggregation at the time of validation.

Data / Parameter	$T_{Aggregate}$
Data unit	Degree Celsius
Description	Temperature of aggregate
Equations	9
Source of data	Estimation based on product requirements, or site specific technical analysis or measurement
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	If from a brownfield site, this parameter may have been measured at the hot mix facility prior to the use of the sulphur extender. If at a greenfield site,or a brownfield site that is not able to measure then default values may be available from industry best practice.
Purpose of data	Calculation of baseline emissions
Comment	The project proponent must ensure that the default value is representative of the type and composition of product used in the project. Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information. For paving segement developers, a method may be specified to determine a parameter for aggregation of multiple paving segments rather than specifying a value for all paving segments included in the aggregation at the time of validation.

Data / Parameter	$T_{Bitumen}$
Data unit	Degree Celsius
Description	Temperature of bitumen
Equation	9
Source of data	Estimation based on product requirements, site specific technical analysis or measurement
Applied value	
Justification of choice of data or description of measurement methods and procedures applied	Default values may be available from industry common practice. May also be measured at the hot mix facility prior to the use of sulphur extender.
Purpose of data	Calculation of baseline emissions
Comment	The project proponent must ensure that the default value is representative of the type and composition of product used in the project. Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information. For paving segement developers, a method may be specified to determine a parameter for aggregation of multiple paving segments rather than specifying a valuefor all segments included in the aggregation at the time of validation.

Data / Parameter	HV_{Fuel}
Data unit	kJ / m^3
Description	Heating value of fuel
Equations	9
Source of data	Value of physical or chemical property
Applied value	
Justification of choice of data or description of measurement methods and procedures applied	Accepted value for the type of fuel used to power the burner.
Purpose of data	Calculation of baseline emissions
Comment	For natural gas the default value is 38 095 kJ/m^3. For other fuel types an appropriate default value should be used. The

	project proponent must ensure that the default value is representative of the type and composition of product used in the project. Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics.

Data / Parameter	Eff
Data unit	%
Description	Fuel combustion and burner efficiency
Equations	9
Source of data	Estimation based on manufacturer specification, site specific technical analysis or measurement
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Efficiencies may be available from manufacturer's specifications or as part of the facility's monitoring processes. In the absence of project-specific data, default values should be used. Default values are high and would result in a conservative estimation of emission reductions.
Purpose of data	Calculation of baseline emissions
Comment	Default values are 80% (combustion) and 80% (burner) for a total efficiency of 64%. The project proponent must ensure that the default value is representative of the type and composition of product used in the project. Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	$Vol\ Fuel_{agg}$
Data unit	L, m^3 or other per kg of aggregate
Description	Volume of fuel combusted for aggregate drying
Equations	9
Source of data	Estimation based on dryer manufacturer specification, site specific technical analysis or measurement
Applied value	
Justification of choice of data or	Value may be obtained from manufacturer specifications

description of measurement methods and procedures applied	for fuel consumption.
Purpose of data	Calculation of baseline emissions
Comment	The project proponent must ensure that the default value is representative of the type and composition of product used in the project. Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information. For paving segement developers, a method may be specified to determine a parameter for aggregation of multiple paving segments rather than specifying a value. for all paving segments included in the aggregation at the time of validation. This value is dependent on the moisture content (%) of the aggregate, and may be estimated based on manufacturer's specifications for fuel consumption.

Data / Parameter	EF Production
Data unit	kg (CO_2, CH_4) per kg of additive
Description	Emission factors for the production of additives
Equations	13
Source of data	Estimation based on additive manufacturer specification or project-specific technical analysis
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Reference values may be obtained from IPCC guidelines. Values are dependent on the production process.
Purpose of data	Calculation of project emissions
Comment	IPCC emission factors are provided in Appendix A, Table A3. The project proponent must ensure that the default value is representative of the type and composition of product used in the project. Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	EF_{Elec}
Data unit	kg CO_2e per kWh
Description	Emissions factor for electricity
Equations	11 and 20
Source of data	Estimation, reference values must be obtained from the relevant national GHG inventory. The value used should be consistent with the source of generation. In the absence of local or regional data, reference values may be obtained from the most recent version of the IPCC guidelines for National Greenhouse Gas Inventories.
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Review of best practice guidance and accepted standards. Reference values are generally available.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	The project proponent must ensure that the default value is representative of the type and composition of product used in the project. Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	$Electricity_{B}$
Data unit	kWh
Description	Electricity used for operating hot mix facility in the baseline
Equations	11
Source of data	Measurement
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Metering of electricity may be direct or by a utility provider. Measurement should be continuous, with monthly aggregation.
Purpose of data	Calculation of baseline emissions
Comment	This parameter may be updated over the course of the

	crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	EF Mixer $_{CO2, B, SS}$, EF Mixer $_{CH4, B, SS}$
Data unit	kg per hour
Description	Mass emission rate of CO_2 and CH_4 from the hot mix stack
Equestions	10 and 19
Source of data	Measurement
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Must be calculated from three years of historical data from third-party sampling of the mass emission rate when the facility was using conventional hot mix asphalt. Direct measurement and average of three years of historical data provides for reasonable quality assurance. It is the responsibility of the project proponent and third party sampler to determine the length of each test and analysis methodology that ensures the accuracy of the sampling procedure. Justification should be provided. The stack sampling of emissions should include only mixing process emissions for any type of plant design (drum or batch mix plants). At least three years of annual stack sampling data should be available from third party sampling when the facility was producing conventional hot mix asphalt for baseline quantification.
Purpose of data	Calculation of baseline emissions Calulcation of project emissions
Any comment	If sampling results are expressed as total organics, conversion to methane may be accomplished by using the default organic composition values of 27% methane for drum mix and 47% methane for batch mix plants, according to guidance provided by the US EPA. The project proponent must ensure that the default value used is representative of the type and composition of product used in the project. Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	$Rate_B$
Data unit	Tonne per hour
Description	Production rate of conventional hot mix asphalt during the stack sampling period
Equations	10
Source of data	Measurement
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Must be calculated from average of three years of historical data from third-party sampling of the mass emission rate when the facility was producing conventional hot mix asphalt. Direct measurement and average of three years of historical data provides for reasonable quality assurance.
Purpose of data	Calculation of baseline emissions
Comment	This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	%CB
Data unit	Percent
Description	Percent of additive in sulphur extender
Equations	13
Source of data	Estimation, default value estimated from sulphur extender production process.
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	May be determined from sulphur extender producer.
Purpose of data	Calculation of project emissions
Comment	This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data Unit / Parameter	$MF_{Bitumen\ B}$
Data unit	kg per tonne of hot mix asphalt produced under the baseline scenario

Description	Mass fraction of bitumen consumed under the baseline scenario
Equations	2, 5 and 9
Source of data	Estimation based on paving segment specifications or measurement
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Default values may be estimated based on available data. The bitumen content of conventional hot mix asphalt may be estimated using: 1. local or regional paving standards or industry data for the type of road being paved; 2. The actual mix composition for the hot mix facility if known. Note that this parameter does not include RAP.
Purpose of data	Calculation of baseline emissions
Comment	These parameters may become out of date. For paving segement developers, aggregation of multiple paving segments may specify a method to determine this parameter for each paving segment rather than specifying a value for all paving segments included in the aggregation at the time of validation.

Data / Parameter	$MF_{Aggregate\ B}$
Data unit	kg per tonne of hot mix asphalt produced under the baseline scenario
Description	Mass fraction of aggregate
Equations	3 and 9
Source of data	Estimation based on project specifications or measurement
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Default values may be obtained from local industry records for the type of road being paved, or actual mix composition for the hot mix facility may be used if known. Note that this parameter does not include RAP.
Purpose of data	Calculation of baseline emissions
Comment	The project proponent must ensure that the default value is representative of the type and composition of product used in the project. Default values must be sourced from

	recognized, credible sources and be geographically and temporally relevant to project specifics. These parameters may become out of date. For paving segement developers, aggregation of multiple paving segments may specify a method to determine this parameter for each paving segment rather than specifying a value for all paving segments included in the aggregation at the time of validation.

9.2 Data and Parameters Monitored

The following data parameters will be monitored during the project.

Data / Parameter	$Mass_{Paving}$
Data unit	tonne
Description	Mass of hot mix asphalt produced
Equations	2, 3, 5, 6, 9, 10 and 19
Source of data	Measurement
Description of measurement methods and procedures to be applied	The project proponent may measure the mass of hot mix asphalt produced in one of three ways: 1. Direct metering ; 2. Reconciliation of quantity delivered to trucks for load-out; 3. Reconciliation of mass of hot mix asphalt applied or distance paved and thickness of paving within a given time period.
Frequency of monitoring/recording	Continuous or per batch, totalized per project with monthly reconciliation if project duration is longer than one month.
QA/QC procedures to be applied	Regular calibration as per requirements of scales ensures quality metering. Cross-checking of metered mass vs. trucking manifests or logs confirms quality measurement on an on-going basis between calibration intervals.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Calculation method	N/A
Comment	None

Data / Parameter	$Vol\ Fuel\ Mixing_{Bitumen}$
Data unit	L, m^3 or other

Description	Volume of each type of fuel combusted during the project for storage of bitumen, drying and hot mixing
Equations	6 and 7
Source of data	Measurement in the project scenario, calculation in the baseline scenario
Description of measurement methods and procedures to be applied	The project proponent may measure the volume of fuel consumed in one of two ways: 1. Direct metering or reconciliation of volumes received and in storage; 2. Reconciliation of volume of fuel purchased within a given time period.
Frequency of monitoring/recording	Totalized per project with monthly reconciliation if project duration is longer than one month.
QA/QC procedures to be applied	Regular calibration and maintenance as per requirements of meter manufacturers ensures quality metering. Cross-checking of metered or purchased volumes vs. theoretical fuel use on annual or quarterly basis. Minor variations should be immaterial on an quarterly or annual basis. Long term trends should align with theoretical expectations and remain consistent on a per volume of product basis.
Purpose of data	Calculation of baseline emissions
Calculation method	N/A
Comment	Overall hot mix facility fuel usage may be used given that bitumen storage, aggregate drying and hot mixing will likely represent the majority of fuel usage for a facility.

Data / Parameter	$Mass_{SE}$
Data unit	kg
Description	Mass of sulphur extender product consumed
Equations	13
Source of data	Measurement
Description of measurement methods and procedures to be applied	The project proponent may measure the mass of sulphur extender in one of two ways: 1. Direct metering or reconciliation of mass received; 2. Reconciliation of mass of sulphur extender purchased within a given time period. This provides a reasonable estimate when direct measurement may not be used.

Frequency of monitoring/recording	Per batch or totalized per project with monthly reconciliation if project duration is longer than one month.
QA/QC procedures to be applied	Regular calibration as per requirements of scales ensures quality metering. Cross-checking of metered mass vs. trucking manifests or logs confirms quality measurement on an on-going basis between calibration intervals.
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comment	None

Data / Parameter	$Mass_{Bitumen}$
Data unit	kg
Description	Mass of bitumen consumed
Equations	14 and 17
Source of data	Measurement
Description of measurement methods and procedures to be applied	The project proponent may measure the mass of bitumen consumed in one of two ways: 1. Direct metering of quantity of bitumen used for hot mixing; 2. Reconciliation of mass received
Frequency of monitoring/recording	Per batch or totalized per project with monthly reconciliation if project duration is longer than one month.
QA/QC procedures to be applied	Regular calibration as per requirements of scales ensures quality metering. Cross-checking of metered mass vs. trucking manifests or logs confirms quality measurement on an on-going basis between calibration intervals.
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comment	None

Data / Parameter	$Mass_{Aggregate}$
Data unit	kg
Description	Mass of aggregate consumed
Equations	15
Source of data	Measurement

Description of measurement methods and procedures to be applied	The project proponent may measure the mass of aggregate consumed in several ways: 1. Direct metering of mass of aggregate consumed at the hot mix facility; 2. Reconciliation of mass received; 3. Calculation as the difference between the mass of hot mix asphalt produced and the sum of mass of binder and all additives consumed; or 4. Reconciliation of mass of aggregate purchased within a given time period.
Frequency of monitoring/recording	Per batch or totalized per project with monthly reconciliation if project duration is longer than one month.
QA/QC procedures to be applied	Regular calibration as per requirements of scales ensures quality metering. Cross-checking of metered mass vs. trucking manifests or logs confirms quality measurement on an on-going basis between calibration intervals.
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comment	None

Data / Parameter	$Electricity_{P}$
Data unit	kWh
Description	Electricity used for operating hot mix facility in the project
Equations	20
Source of data	Measurement
Description of measurement methods and procedures to be applied	Metering of electricity may be direct or by a utility provider. Measurement should be continuous, with monthly aggregation.
Frequency of monitoring/recording	Totalized per project with monthly reconciliation if project duration is longer than one month.
QA/QC procedures to be applied	Electricity utility standard maintenance and calibration procedures apply. Cross-checking of metered values versus engineering estimates or theoretical electricity usage values ensures accuracy between calibration intervals.
Purpose of data	Calculation of project emissions
Calculation method	N/A

Comment	None

Data / Parameter	EF Mixer $_{CO2, SS}$, EF Mixer $_{CH4, SS}$
Data unit	kg per hour
Description	Mass emission rate of CO_2 and CH_4 from the hot mix stack
	19
Source of data	Measurement
Description of measurement methods and procedures to be applied	Sampling on an annual basis by a third party. Direct measurement with this sampling frequency provide for reasonable quality assurance. Stack monitoring should be conducted at a point that includes process emissions from mixing only, and may not include ducted emissions from fuel combustion or any other emission source from the facility.
Frequency of monitoring/recording	At least annually
QA/QC procedures to be applied	Regular calibration and maintenance as per requirements of meter manufacturers ensures quality metering. Cross-checking of metered values versus engineering estimates or theoretical emission values ensures accuracy between calibration intervals. It is the responsibility of the project proponent and third party sampler to determine the length of each test and analysis methodology that ensures the accuracy of the sampling procedure. Justification should be provided. The stack sampling of emissions should include only mixing process emissions for any type of plant design (drum or batch mix plants). At least three years of annual stack sampling data should be available from third party sampling when the facility was producing conventional hot mix asphalt for baseline quantification.
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comment	If sampling results are expressed as total organics, conversion to methane may be accomplished by using the default organic composition values of 27% methane for drum mix and 47% methane for batch mix plants, according to guidance provided by the US EPA. The project proponent must ensure that the default value used is representative of the type and composition of product

	used in the project. Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	Rate
Data unit	Tonne per hour
Description	Production rate of hot mix asphalt during the stack sampling period
Equations	19
Source of data	Measurement
Description of measurement methods and procedures to be applied	Sampling on an annual basis by a third party. Direct measurement and this sampling frequency provides for reasonable quality assurance
Frequency of monitoring/recording	Frequency to match EF Mixer $_{CO2,\ SS}$, EF Mixer $_{CH4,\ SS}$ sampling frequency
QA/QC procedures to be applied	Regular calibration as per requirements of scales ensures quality metering. Cross-checking of metered mass vs. trucking manifests or logs confirms quality measurement on an on-going basis between calibration intervals.
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comment	None

9.3 Description of the Monitoring Plan

The project proponent must develop a monitoring plan detailing the procedures for data capture, measurement and reporting of all the data parameters listed in Section 9.2. In general, data quality management must include sufficient data capture such that the mass and energy balances may be easily performed with the need for minimal assumptions and use of contingency procedures. The data should be of sufficient quality to fulfill the quantification requirement and be substantiated by company records for the purpose of verification.

The project proponent must establish and apply quality management procedures to manage data and information. Written procedures should be established for each measurement task outlining responsibility, timing and record location requirements. The greater the rigour of the management system for the data, the more easily an audit will be conducted for the project.

Record keeping practices must be established that include:

- Electronic recording of values of logged primary parameters for each measurement interval;
- Printing of monthly back-up hard copies of all logged data;
- Written logs of operations and maintenance of the project system including notation of all shut-downs, start-ups and process adjustments;
- Retention of copies of logs and all logged data for at least two years after the end of the crediting period; and
- Keeping all records available for review by a validation/verification body.

The project proponent must also develop a QA/QC plan to add confidence that all measurements and calculations have been made correctly. QA/QC measures that may be implemented include, but are not limited to:

- Protecting monitoring equipment (eg, temperature gauges)
- Protecting records of monitored data (hard copy and electronic storage) – appropriate record keeping and retention;
- Checking data integrity on a regular and periodic basis (manual assessment, comparing redundant metered data, and detection of outstanding data/records) done to ensure mix formulation is followed and to ensure appropriate payments are made (pay only for what is delivered to site);
- Providing sufficient training to operators to perform maintenance and calibration of monitoring devices as road building staff must have appropriate training to operate the mix plant in such a manner to ensure the right mix is created, meeting the road agency's specifications;
- Establish minimum experience and requirements for operators in charge of project and monitoring; and
- Performing recalculations to make sure no mathematical errors have been made.

In general, data accuracy is inherently addressed in this methodology because the inputs into road-building are metered to ensure mix specifications are met. There is a high degree of certainty in the measurements of binder and aggregate employed to ensure quality of product. Operating temperatures are also closely monitored due to worker health and safety regulatory requirements, and to ensure no wastage of fuel. Fuel quality specifications are provided upon purchase, and these provide the parameters necessary to calculate fuel GHG intensity. The costs of all the inputs into the road are also borne by the contractor, and are monitored and recorded to ensure appropriate payments and cost recoveries are made. The nature of road-building projects therefore provides a high degree of confidence in the data used with the methodology, and addresses significant uncertainties.

- Parameters relevant to the project quantification for which confidence intervals cannot easily be generated include those listed below. Project proponents must demonstrate the factors or values used in the project are appropriately conservative based on the uncertainty of the actual parameter during the project.$T_{hot\ mix}$
- $T_{aggregate}$
- $T_{bitumen}$
- $MF_{bit,\ B}$
- $EF_{Agg,\ x}$
- $EF_{Bit\ Production,\ x}$
- $MF_{Aggregate,\ B}$
- EF Mixer $_{CH4}$
- EF $_{Fuel,\ i,\ x}$
- Eff
- Vol Fuel $_{agg,\ i}$
- EF Production$_{x}$
- EF_{Elec}
- %CB

Methods used by the project proponent for estimating uncertainty should be based on recognized statistical approaches such as those described in the *IPCC Good Practice Guidance and Uncertainty Management in National Greenhouse Gas Inventories*. Where applicable, confidence deductions applied should use conservative factors such as those specified in the CDM Methodology Panel guidance on addressing uncertainty in its *Thirty Second Meeting Report*, Annex 14.

The project proponent should address uncertainties in measured values by ensuring that meters are appropriately calibrated as prescribed by the manufacturer.

APPENDIX 1: EMISSIONS FACTORS

Bitumen Production

Values for bitumen production as listed below in Table A1 were obtained from volume 1 of the technical report *A National Inventory of Greenhouse Gas (GHG), Criteria Air Contaminant (CAC) and Hydrogen Sulphide (H_2S) Emissions by the Upstream Oil and Gas Industry* dated September 2004 completed by Clearstone Engineering Ltd. on behalf of the Canadian Association of Petroleum Producers (CAPP). These values were taken from Table 4, entitled 'Summary of emission intensity factors presented by sub-sector of the UOG sector for 2000'. These emissions factors are typical for bitumen production in Canada, and may vary according to geographic location and the refinery. The project proponent must ensure that the emission factors used are applicable to the project.

Table A1: Emission Intensity of Bitumen Production

Heavy Crude Thermal Production		
Emissions Factor (CO_2)	594.2	kg CO_2 / m^3
Emissions Factor (CH_4)	3.75	kg CH_4 / m^3
Emissions Factor (N_2O)	0.009	kg N_2O / m^3

Hot Mixing

Emission factors for hot mixing listed below in Table A2 were derived from the fifth edition of the US EPA's AP-42, *Compilation of Air Pollutant Emission Factors*. In Volume 1: *Stationary Point and Area Sources - Chapter 11.1 (Hot Mix Asphalt Plants),* dated April 2004. Emission factor units for methane are kg/Mg of hot mix asphalt produced.[1]

Table A2: Emission Intensity of Hot Mixing

Plant Type	CH_4	Units
Natural Gas Batch	0.0037	kg / Mg of HMA produced
Natural Gas Drum Mix	0.006	kg / Mg of HMA produced
No. 2 Fuel Oil Batch Mixer	0.0037	kg / Mg of HMA produced
No. 2 Fuel Oil Drum Mixer	0.006	kg / Mg of HMA produced

Carbon Black Production

Values for carbon black production listed below in Table A3 were obtained from the 2006 IPCC Guidelines for National Greenhouse Gas Inventories, Volume 3: Industrial Processes and Product Use.[2]

[1] Information retrieved from Table 11.1-6 and Table 11.1-8, for batch or drum mix, respectively.
[2] Please refer to Table 3.23 and 3.24

The majority of the world's carbon black is produced by the furnace black process. Emission factors for both production methods are equivalent.

Table A3: Emission Intensity of Carbon Black Production

Production Process	CO_2			Units
	Primary Feedstock	Secondary Feedstock	Total Feedstock	
Furnace Black	1.96	0.66	2.62	kg / kg carbon black
Thermal	4.59	0.66	5.25	kg / kg carbon black
Production Process	CH_4			Units
No Thermal Treatment	0.0287			kg / kg carbon black
Thermal treatment (default)	0.00006			kg / kg carbon black

Methodology for Precast Concrete Production using Sulphur Substitute

Version 1.0

15 May 2015

Sectoral Scopes 4 & 6

Methodology developed by:

Shell Malaysia Trading Sdn Bhd

In partnership with:

Cap-Op Energy Inc.

Viresco Solutions Inc.

Table of Contents

1 SOURCES

This methodology is based on the draft *Quantification Protocol for the Use of Sulphur Concrete in Precast Applications v0.4*, issued under the Alberta Specified Gas Emitters Regulation. The methodology references the following CDM tools:

- *Combined tool to identify the baseline scenario and demonstrate additionality*
- *Tool for the demonstration and assessment of additionality*

In addition, technical and good practice guidance was obtained from Environment Canada's annual GHG reporting, the US EPA's Emission Inventory, the Intergovernmental Panel on Climate Change (IPCC), and various other reliable sources of information pertaining to the concrete production industry. The good practice guidance and best science used to develop the quantification methodology are presented in Section 10.

2 SUMMARY DESCRIPTION OF THE METHODOLOGY

Additionality and Crediting Method	
Additionality	Project Method
Crediting Baseline	Project Method

Concrete is a commonly used material for infrastructure, industrial and construction applications, consisting of aggregate (rock and sand), water and cement. The production of calcium and/or magnesium carbonate-derived cement (often from limestone) releases significant amounts of greenhouse gases (GHG).

Traditional cementitious binders derived from limestone and clay rely on the chemical bonds formed upon contact with water to bind together aggregate material (sand and rock) to form concrete. This binder (clinker) is a key component of cement. The production of clinker results in the release of a significant amount of GHG from two main sources: process emissions and combustion emissions. Carbon dioxide process emissions occur as a by-product of the calcination process, where a calcium or magnesium carbonate such as limestone is heated with clay to form clinker (primarily calcium oxide) and carbon dioxide. Additional GHG emissions occur because heat for the calcination process is normally supplied via the combustion of fossil fuels, releasing carbon dioxide, methane and nitrous oxide as a result.

Portland cement can be completely substituted with modified heated sulphur to form a stable, hard concrete product, avoiding the process and combustion emissions associated with the manufacture of Portland cement.

This methodology is applicable to processes that involve the substitution of calcium and/or magnesium carbonate-derived cement, known as Portland cement, with an alternative binder, such as a modified heated sulphur product, during the production of concrete and other concrete-based products such as pre-cast pipe, paving stones, slabs and tanks. This methodology is not applicable to projects employing standard poured-in-place concrete production processes, or supplementary cementing material (SCM) products.

For the purposes of this methodology, a project is considered a set or series of pre-cast concrete products, produced at one facility, where the pre-cast products have similar functional specifications to the same pre-cast products in the baseline scenario. The project may consist of emission reductions from several product sets or series if they are all cast at the same facility, provided the baseline scenario selected is appropriate for all products to be included in the project.

The baseline scenario is specified as the production of concrete using traditional cementitious binders derived from limestone and clay that rely on the chemical bonds formed upon contact with water to bind together aggregate material (sand and rock). This binder (clinker) is a key component of Portland cement.

The project proponent may be the technology owner, facility owner, agent or otherwise of products produced with sulphur concrete. Right of use must be established and demonstrated at the project level as specified and required by the VCS rules. Where the project proponent is not the owner of the precast concrete facility (eg, is the technology owner, agent of the products produced, or the end user), there must exist a contractual agreement, or otherwise, between the project proponent and the relevant parties to avoid the risk of double counting with other participants in the supply chain. Note that as emission reductions generated by projects that apply this methodology are attributed partly to indirect emission from electricity production, projects developed in jurisdictions that have cap-and-trade programs require assessment to ensure double counting does not occur. Therefore, the project proponent must be aware of the VCS rules on double counting when a proposed project occurs in a jurisdiction with a cap and trade program covering the electrivity sector, which might render the project unviable.

3 DEFINITIONS

In addition to the definitions set out in VCS document *Program Definitions*, the following definitions apply to this methodology:

Aggregate
Materials or substances that are included in an concrete product which do not serve to bind the aggregate, rather they facilitate or modify the binder (or binder substitute) properties to better meet production requirements or product specifications.
Aggregates including fly ash and slag are cementitious materials partially displacing Portland cement in the baseline product, however can also be included in sulphur concrete products.

Binder
Material that serves as an adhesive that binds with the aggregate to form concrete

Concrete
Composite building material made from the combination of aggregate and a cement binder

Portland Cement
Finely ground, usually grey-coloured mineral powder that when mixed with water, acts as a glue to bind together aggregate to form concrete

Precast Products
Form of construction where concrete is cast in a reusable mould or form, which is then cured in a controlled environment. Examples of precast products include paving stones, planters, traffic barriers, holding tanks and retaining walls, among many others.

Sulphur Cement
Product composed of molten elemental sulphur and a proprietary modifier that acts as a glue to bind together aggregate to form sulphur concrete. Sulphur cement requires no water to form sulphur concrete.

4 APPLICABILITY CONDITIONS

This methodology is applicable to the production of sulphur concrete for precast applications where the following conditions are met:

1. The baseline scenario is the production of precast concrete products using Portland cement, as demonstrated using the procedure set out in Section 6.
2. The project activity may take place at existing (retrofitted) or new (greenfield) precast concrete production facilities.
3. The use of recycled concrete is not eligible in either the baseline or project scenario.
4. The handling, storage, mix production temperature and other key factors specified by the manufacturer for the proper and safe use of sulphur cement have been followed by the project proponent.
5. The resulting sulphur concrete product meets all applicable legal and technical requirements. In the absence of technical specifications for concrete, the project proponent must demonstrate that sulphur concrete produced under the project scenario provides the equivalent function to concrete that would have been produced under the baseline scenario.
6. The pouring and forming processes must be comparable between the baseline and project scenarios for an equivalent product. The quantity of aggregate used (on a mass basis) in the baseline scenario must be comparable to the quantity of aggregate used in the project scenario for an equivalent product.

7. For projects that consist of multiple project activity instances (ie, multiple pre-cast concrete production lines), all concrete used and all concrete products must have been produced from the same facility.

5 PROJECT BOUNDARY

Sources, sinks and reservoirs (SSRs) included in project and baseline quantification include those that are within the project site (the physical, geographic location of the cement production facility), as well as others that are off-site.

The project proponent must account for:

- Direct emissions avoided by displacing Portland cement production and use with sulphur cement production and use
- Direct emissions due to fuel combustion at the precast concrete facility for:
    - Heating of aggregate.
    - Additional heating of the sulphur additive.
- Direct emissions due to fuel combustion and process emissions outside the precast concrete facility for:
    - Production of the sulphur modifier;.
    - Transport of the modifier and modified sulphur product.
- Indirect emissions due to the generation of electricity generation (if applicable).
- Indirect emissions due to the degassing of sulphur (if applicable).

A generalized process flow diagram of a typical project and baseline are presented in below Figure 1 and Figure 2 respectively.

Figure 1: Flow Diagram of Baseline Emissions

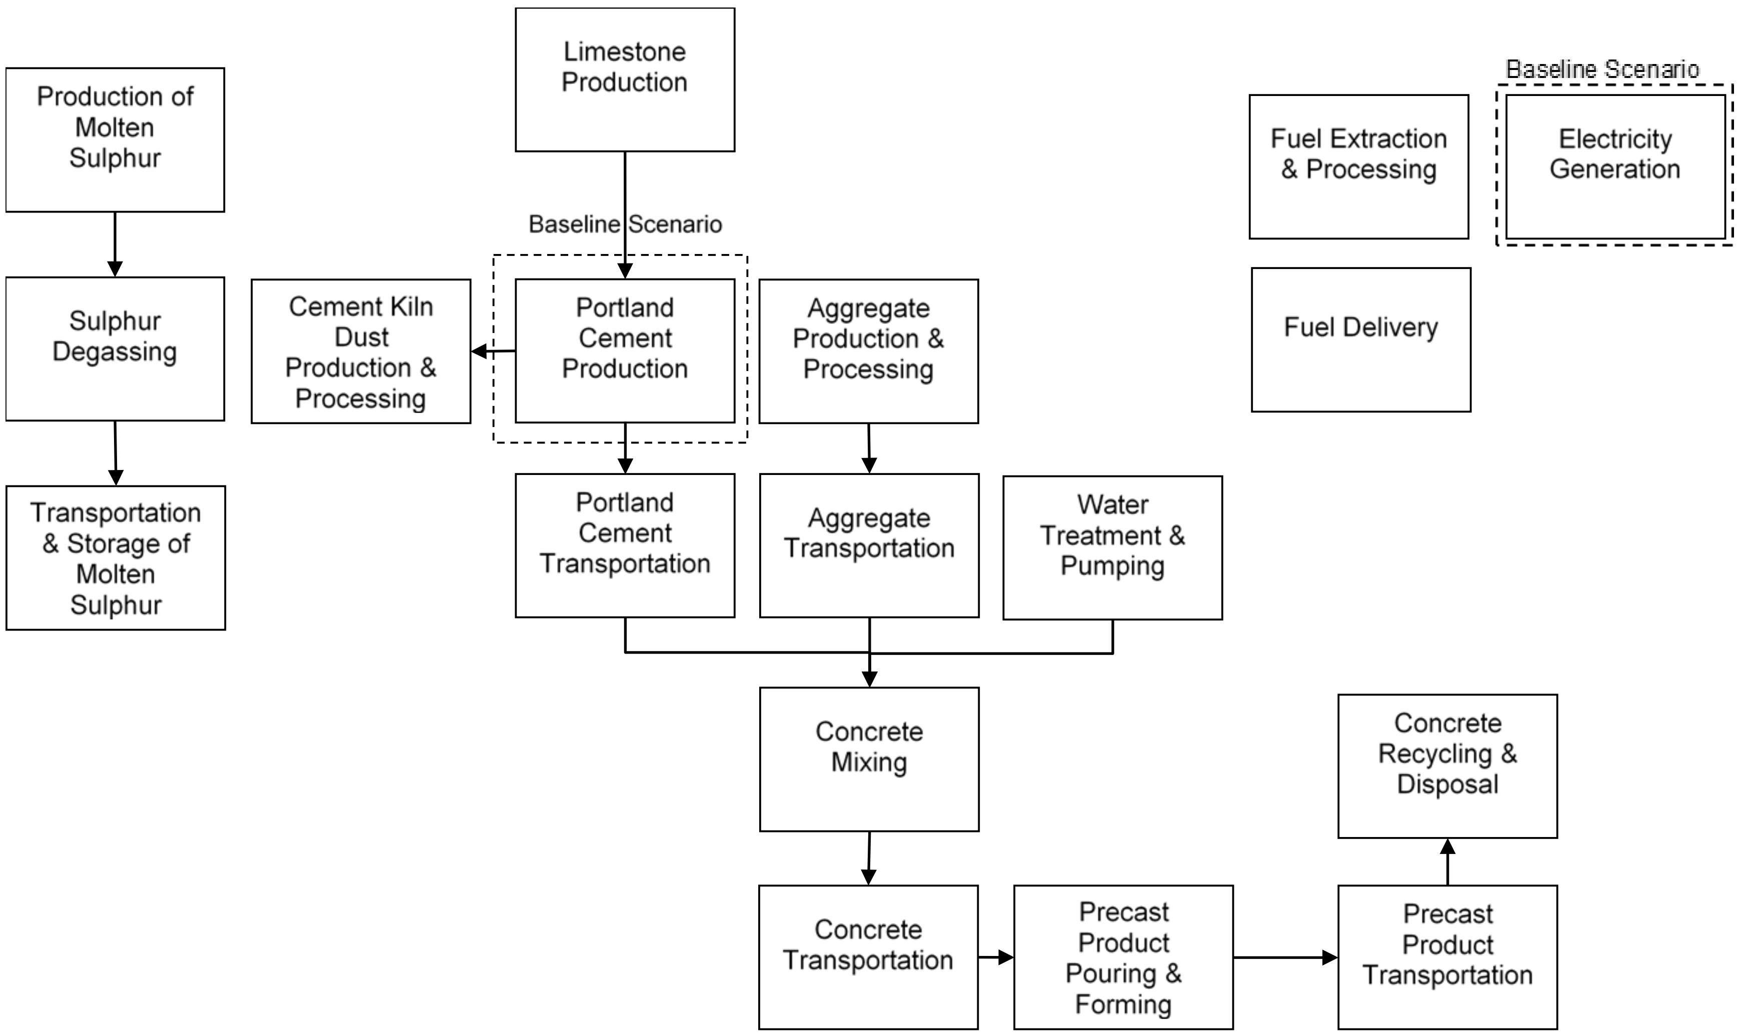

Figure 2: Flow Diagram of Project Emissions

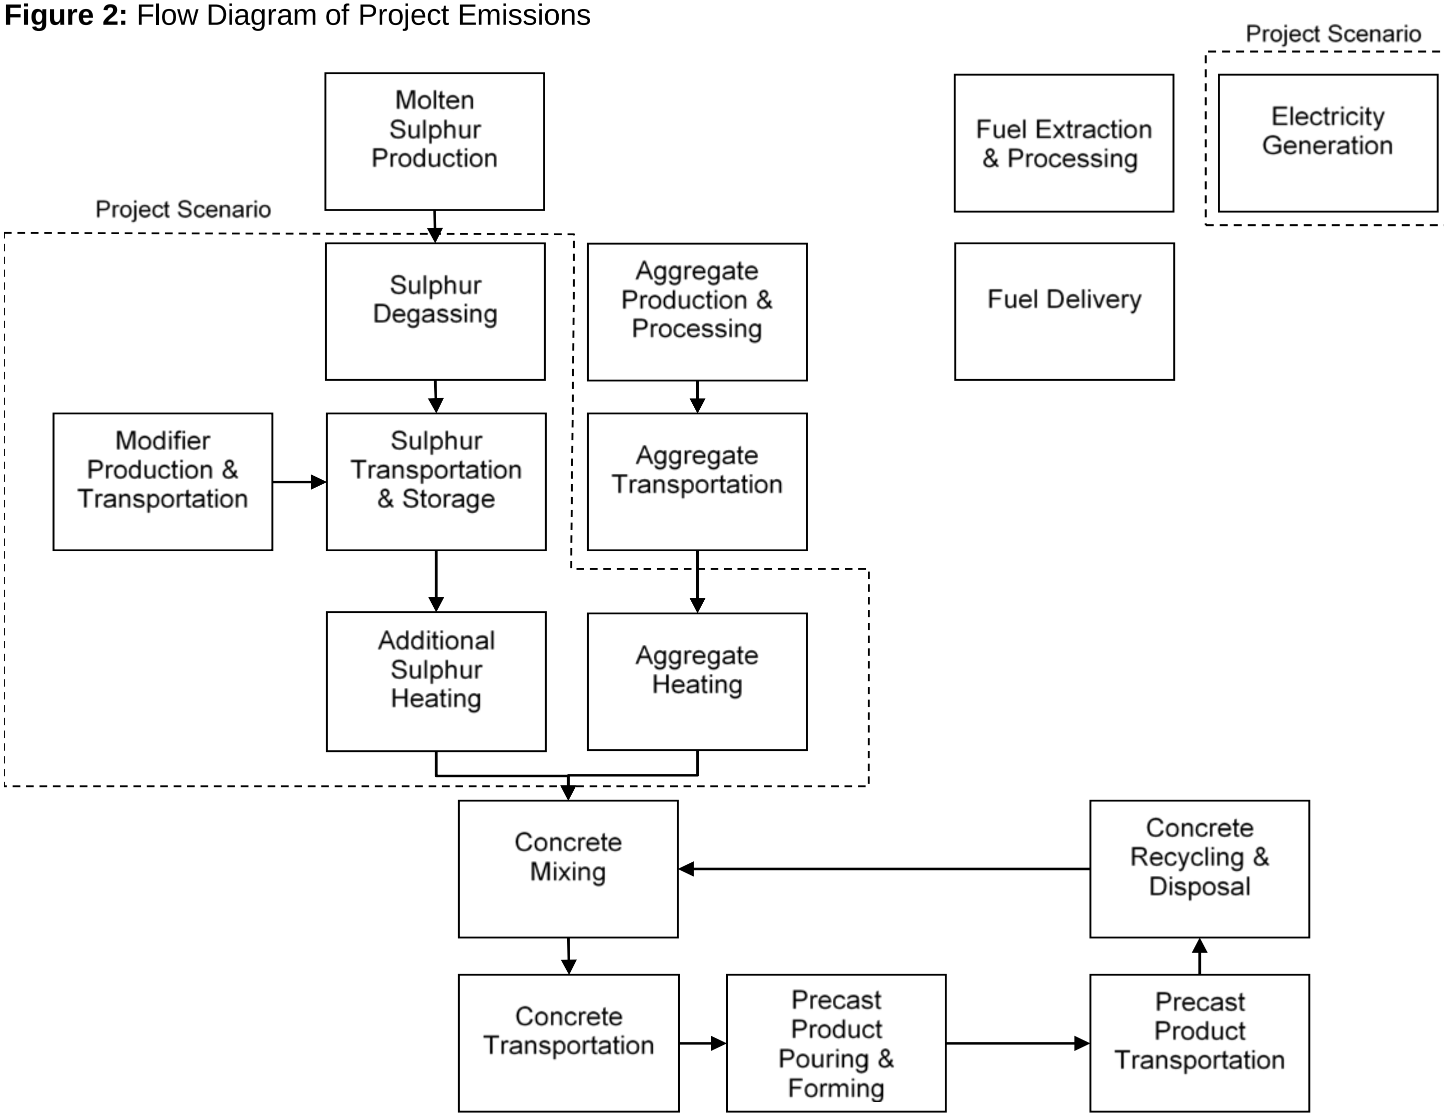

The SSRs represented in Figures 1 and 2 above were compared and the relevancy evaluated to determine if they must be included or excluded from the quantification methodology. Table 1 below provides justification for the inclusion or exclusion of each of the potential SSRs in the project and baseline scenarios. The project proponent must justify the baseline and project SSRs selected for quantification in the project.

Table 1: GHG Sources, Sinks and Reservoirs

Source		Controlled, Related, or Affected	Gas	Included	Justification/Explanation
Baseline	Production of molten sulphur	Related	CO_2	No	Excluded as the quantity of molten sulphur produced in the project and baseline scenarios are functionally equivalent. Sulphur is a by-product of gas processing and petroleum refining and would be produced in both the project and baseline scenarios in the same quantity.
			CH_4	No	
			N_2O	No	
	Sulphur degassing	Related	CO_2	No	If sulphur degassing was occurring in the baseline scenario, it will continue under the project scenario and emissions will be equivalent. Project-specific emissions from sulphur degassing are accounted for in the project scenario, therefore it is conservative to exclude this SSR.
			CH_4	No	
			N_2O	No	
	Transportation and storage of molten sulphur	Related	CO_2	No	If transportation and storage of molten sulphur was occurring in the baseline, it will continue under the project scenario and will be equivalent. Project-specific emissions from the transportation and storage of molten sulphur are accounted for in the project scenario, therefore it is conservative to exclude this SSR.
			CH_4	No	
			N_2O	No	
	Limestone production	Related	CO_2	No	Less limestone will be produced in the project scenario and therefore emissions will be lower in the project scenario. The emissions from this SSR are relatively low and difficult to estimate accurately. Exclusion of this SSR is conservative.
			CH_4	No	
			N_2O	No	
	Portland cement	Related	CO_2	Yes	The production of Portland cement in the baseline scenario has relevant emissions and
			CH_4	Yes	

Source		Controlled, Related, or Affected	Gas	Included	Justification/Explanation
	production		N_2O	Yes	must be included.
	Cement kiln dust production and processing	Related	CO_2	No	Cement kiln dust (CKD) refers to the portion of the cement raw materials that does not become part of the clinker. CO_2 might be emitted from CKD that is not recycled to the Portland cement production process. CKD is not produced in the project scenario, therefore it is conservative to exclude its production and processing related emissions.
			CH_4	No	
			N_2O	No	
	Portland cement transportation	Related	CO_2	No	The quantity of Portland cement that is transported in the project scenario would be less than the quantity in the baseline scenario; therefore it is conservative to exclude these emissions.
			CH_4	No	
			N_2O	No	
	Aggregate production and processing	Related	CO_2	No	Excluded as the same quantity of aggregate would be produced and processed in the project and baseline scenarios.
			CH_4	No	
			N_2O	No	
	Transportation of aggregate	Related	CO_2	No	Excluded as the same quantity of aggregate would be transported in the project and baseline scenarios.
			CH_4	No	
			N_2O	No	
	Water treatment and pumping	Related	CO_2	No	Emissions from this SSR are avoided in the project scenario. This emission reduction is not the focus of this methodology. Emissions are excluded as it is conservative to do so.
			CH_4	No	
			N_2O	No	
	Fuel extraction/processing	Related	CO_2	No	Fuel production and extraction emissions are higher in the baseline than in the project and hence conservative to exclude.
			CH_4	No	
			N_2O	No	
	Fuel delivery	Related	CO_2	No	The quantity of fuel consumed in the baseline scenario for the production of Portland cement will be greater than the quantity of fuel consumed in the project scenario for mixing sulphur concrete. Emissions are excluded as it is conservative to do so.
			CH_4	No	
			N_2O	No	
	Electricity generation	Related	CO_2	Yes	Indirect emissions from electricity use may be a significant source of emissions. The project
			CH_4	Yes	

Source		Controlled, Related, or Affected	Gas	Included	Justification/Explanation
			N_2O	Yes	proponent must include electricity in the methodology if it is demonstrated to be conservative.
	Concrete mixing	Controlled	CO_2	No	The process for concrete mixing is equivalent in the baseline and project scenarios.
			CH_4	No	
			N_2O	No	
	Concrete transportation	Controlled	CO_2	No	The same quantity of concrete will be transported in the baseline and project scenarios.
			CH_4	No	
			N_2O	No	
	Precast product pouring and forming	Controlled	CO_2	No	The process for pouring and forming will not change between the baseline and project scenarios.
			CH_4	No	
			N_2O	No	
	Precast product transportation	Affected	CO_2	No	There is no difference in the transportation related emissions between the baseline and project scenarios.
			CH_4	No	
			N_2O	No	
	Concrete recycling or disposal	Affected	CO_2	No	Excluded for simplification. Recycling emission reductions are not applicable to this method and disposal emissions are equivalent between project and baseline.
			CH_4	No	
			N_2O	No	
Project	Production of molten sulphur	Related	CO_2	No	Excluded as the quantity of molten sulphur produced in the project and baseline scenarios are functionally equivalent. Sulphur is a by-product of gas processing and would be produced in both the project and baseline scenarios in the same quantity
			CH_4	No	
			N_2O	No	
	Sulphur degassing	Related	CO_2	Yes	If sulphur degassing is occurring as a result of the project and the producer would otherwise not be degassing the sulphur, the emissions will be additional to the baseline scenario.
			CH_4	Yes	
			N_2O	Yes	
	Transportation and storage of molten sulphur	Related	CO_2	Yes	Transportation and storage emissions in the project scenario are deemed to be additional to baseline scenario transportation and storage and must be included.
			CH_4	Yes	
			N_2O	Yes	
	Modifier	Related	CO_2	Yes	Emissions associated with the production and

Source		Controlled, Related, or Affected	Gas	Included	Justification/Explanation
	production and transportation		CH_4	Yes	transportation of the sulphur modifier is directly related to the project and must be included.
			N_2O	Yes	
	Aggregate production and processing	Related	CO_2	No	Excluded as the same quantity of aggregate would be produced and processed in the project and baseline scenarios.
			CH_4	No	
			N_2O	No	
	Transportation of aggregate	Related	CO_2	No	Excluded as the same quantity of aggregate would be transported in the project and baseline scenarios.
			CH_4	No	
			N_2O	No	
	Fuel extraction and processing	Related	CO_2	No	Fuel extraction and production used for Additional sulphur heating in the project will be less than baseline fuel extraction and production and therefore conservative to exclude.
			CH_4	No	
			N_2O	No	
	Fuel delivery	Related	CO_2	No	Excluded as the emissions from transportation are likely negligible.
			CH_4	No	
			N_2O	No	
	Electricity generation	Related	CO_2	Yes	Indirect emissions from electricity use may be a significant source of emissions. The project proponent must include electricity in the methodology if it is demonstrated to be conservative.
			CH_4	Yes	
			N_2O	Yes	
	Additional sulphur heating	Controlled	CO_2	Yes	Any heat derived from sources that emit greenhouse gases is additional to the baseline scenario and must be included.
			CH_4	Yes	
			N_2O	Yes	
	Aggregate heating	Controlled	CO_2	Yes	Any heat derived from sources that emit greenhouse gases is additional to the baseline scenario and must be included.
			CH_4	Yes	
			N_2O	Yes	
	Concrete mixing	Controlled	CO_2	No	The process for concrete mixing is equivalent in the baseline and project scenarios.
			CH_4	No	
			N_2O	No	
	Concrete transportation	Controlled	CO_2	No	The same quantity of concrete will be transported in the baseline and project
			CH_4	No	

Source		Controlled, Related, or Affected	Gas	Included	Justification/Explanation
			N_2O	No	scenarios.
	Precast product pouring and forming	Controlled	CO_2	No	The process for pouring and forming will not change between the baseline and project scenarios.
			CH_4	No	
			N_2O	No	
	Precast product transportation	Controlled	CO_2	No	There is no difference in the transportation related emissions between the baseline and project scenarios.
			CH_4	No	
			N_2O	No	
	Concrete recycling or disposal	Controlled	CO_2	No	Excluded for simplification. Recycling emission reductions are not applicable to this method and disposal emissions are equivalent between project and baseline.
			CH_4	No	
			N_2O	No	

*Gas types listed are those that are relevant at least once to the project or baseline scenario. No refrigerants are relevant to this methodology.

The temporal project boundary includes the operation of an existing or new precast concrete facility during the incorporation of a sulphur binder. SSRs related to the construction and decommissioning of the facility are considered outside the scope of this methodology and have been excluded from quantification. This is reasonable given the minimal emissions associated with the construction and decommissioning phases and the long operational life of the facility.

6 PROCEDURE FOR DETERMINING THE BASELINE SCENARIO

The baseline scenario for projects applying this methodology is the production of precast concrete products using Portland cement. The project proponent must demonstrate that this is the most reasonable and credible baseline for their project using the most recent version of the CDM tool *Combined tool to identify the baseline scenario and determine additionality*. The project proponent must use this tool to identify all realistic and credible baseline alternatives, and to identify barriers and to assess which alternatives are prevented by these barriers. In doing so, relevant local regulations governing the use of different technologies, and technical specifications of concrete products must be taken into account.

7 PROCEDURE FOR DEMONSTRATING ADDITIONALITY

Additionality must be assessed and demonstrated using the latest version of the CDM tools *Combined tool to identify the baseline scenario and demonstrate additionality* or *Tool for the demonstration and assessment of additionality.*

8 QUANTIFICATION OF GHG EMISSION REDUCTIONS AND REMOVALS

8.1 Baseline Emissions

The production of clinker results in the release of significant process GHG emissions and combustion GHG emissions. Carbon dioxide process emissions occur as a by-product of the calcination process, where a calcium or magnesium carbonate such as limestone is heated with clay to form clinker (primarily calcium oxide) and carbon dioxide. The heat required for the calcination process is typically supplied from the combustion of fossil fuels, resulting in the emission of further carbon dioxide as well as smaller amounts of methane and nitrous oxide.

Baseline quantification in this methodology is projection based, which uses projections of reductions or removals in the project to estimate the baseline activity that would have occurred in the absence of the project. The calculation of the emissions related to the production of Portland cement in the baseline scenario will be based on the mass of sulphur cement used in the project scenario. An equivalency factor will be used to provide functional equivalence between the mass of sulphur cement and Portland cement. Finally, an emission factor representing the mass of carbon dioxide equivalent greenhouse gas emissions per tonne of Portland cement displaced will be applied.

Emissions under the baseline scenario (in tonnes CO_2e) are determined using the following equation:

$$BE_y = \frac{BE_{Portland} + BE_{Electricity}}{1000} \quad (1)$$

Where:

BE_y = Baseline emissions in a given year (y) (t CO_2e)

$BE_{Portland}$ = Emissions due to the production of Portland cement (kg CO_2e)

$BE_{Electricity}$ = Emissions due to electricity generation for the production of Portland cement (kg CO_2e)

The emissions due to the production of Portland cement under the baseline scenario are calculated as follows:

$$BE_{Portland} = Mass_{Precast} \times \%_{PC} \times EF_{Portland\ Cement\ Production} \quad (2)$$

Where:

$BE_{Portland}$ = Emissions due to the production of Portland cement (kg CO_2e)

$Mass_{Precast}$ = Mass of finished precast products containing sulphur cement (t)

$\%_{PC}$ = Ratio of Portland cement used in the finished precast product (unitless)

$EF_{Portland\ Cement\ Production}$ = Emission factor for the production of Portland cement (kg CO_2e/t)

The emission factor for Portland cement production are calculated as follows:

$$EF_{Portland\ Cement\ Production} = \frac{Mass_{Clinker}}{Mass_{Cement}} \times EF_{Clinker} \quad (3)$$

Where:

$EF_{Portland\ Cement\ Production}$ = Emission factor for the production of Portland cement (kg CO_2e/t)

$Mass_{Clinker}/Mass_{Cement}$ = Clinker to cement ratio (unitless)

$EF_{Clinker}$ = Emission factor of clinker (kg CO_2e/t)

The emissions due to electricity generation for the production of Portland cement under the baseline scenario are as follows:

$$BE_{Electricity} = Electricity_{B} \times EF_{Elec} \quad (4)$$

Where:

$BE_{Electricity}$ = Emissions due to electricity generation for the production of Portland cement (kg CO_2e)

$Electricity_{B}$ = Electricity used for the production of Portland cement (kWh)

EF_{Elec} = Emissions factor for electricity (kg CO_2e/kWh)

8.2 Project Emissions

Emissions under the project scenario (in tonnes CO_2e) are determined using the following equation:

$$PE_y = \frac{PE_{Degassing} + PE_{Additional\ S\ Heating} + PE_{Agg\ Heating} + PE_{S\ Trans\&Storage} + PE_{Modifier} + PE_{Elec}}{1000} \quad (5)$$

Where:

PE_y = Project emissions in a given year (y)

$PE_{Degassing}$ = Emissions due to sulphur degassing (kg CO_2e)

$PE_{Additional\ S\ Heating}$ = Emissions due to the additional heating requirements of sulphur concrete (kg CO_2e)

$PE_{Agg\ Heating}$ = Emissions due to heating the aggregate (kg CO_2e)

$PE_{STrans\&Storage}$ = Emissions due to the transportation and storage of sulphur (kg CO_2e)

$PE_{Modifier}$ = Emissions due to the production and transportation of the sulphur modifier (kg CO_2e)

$PE_{Electricity}$	=	Emissions due to the generation of electricity for use in the precast sulphur concrete facility (kg CO_2e)

The emissions due to sulphur degassing under the project scenario are calculated as follows:

$$PE_{Degassing} = \sum_{x,k}\left(Vol\ Fuel_{DG,k} \times EF\ Fuel_{k,x} \times GWP_x\right) + \left(Vol_{vent\ gas} \times MF_{CO2} \times \frac{m_{CO2}}{V_{STP}}\right) \quad (6)$$

Where:

$PE_{Degassing}$	=	Emissions due to sulphur degassing (kg CO_2e)
Vol $Fuel_{k,DG}$	=	Volume of each type of fuel combusted for degassing (L, m^3 or other)
EF $Fuel_{k,x}$	=	Emissions factor for fuel combustion for each type of fuel (k) used and GHG (x) listed (kg CO_2e/L, m^3 or other)
$Vol_{vent\ gas}$	=	volume of degassing vent gas incinerated (m^3)
MF_{CO2}	=	Molar fraction of CO_2 in degassing vent gas incinerated (%)
M_{CO2}	=	Molar mass of CO_2 (kg/mol)
V_{STP}	=	Volume of one kg-mole of an ideal gas at standard temperature and pressure (m^3)
GWP_x	=	Global warming potential for each GHG (kg CO_2e)
x	=	Value for each GHG (CO_2, CH_4 and N_2O)

The emissions for additional heating of sulphur are calculated as follows:

$$PE_{Additional\ S\ Heating} = \sum_{x,k}\left(Vol\ Fuel_{AH,k} \times EF\ Fuel_{k,x} \times GWP_x\right) \quad (7)$$

Where:

$PE_{Additional\ S\ Heating}$	=	Emissions due to the additional heating requirements of sulphur concrete (kg CO_2e)
$VolFuel_{k,AH}$	=	the volume of each type of fuel combusted for additional sulphur heating (L, m^3 or other)
EF $Fuel_{k,x}$	=	the emissions factor for fuel combustion for each type of fuel (k) used and GHG (x) listed (kg CO_2e/L, m^3 or other)
GWP_x	=	Global warming potential for each GHG (kg CO_2e)
x	=	Value for each GHG (CO_2, CH_4 and N_2O)

The emissions for heating of aggregate are calculated as follows:

$$PE_{Agg\ Heating} = \sum_{x,k}\left(Vol\ Fuel_{AG,k} \times EF\ Fuel_{k,x} \times GWP_x\right) \quad (8)$$

Where:

$PE_{Agg\ Heating}$	=	Emissions due to heating the aggregate (kg CO_2e)
$VolFuel_{k,AG}$	=	Volume of each type of fuel combusted for aggregate heating (L, m^3 or other)
$EF\ Fuel_{k,x}$	=	Emissions factor for fuel combustion for each type of fuel (k) used and GHG (x) listed (kg CO_2e/L, m^3 or other)
GWP_x	=	Global warming potential for each GHG (kg CO_2e)
x	=	Value for each GHG (CO_2, CH_4 and N_2O)

The emissions due to transportation and storage of molten sulphur under the project scenario are calculated as follows:

$$PE_{S\ Trans\&Storage} = Mass\ Distance \times EF_{Transport} \quad (9)$$

Where:

$PE_{STrans\&Storage}$	=	Emissions due to the transportation and storage of sulphur (kg CO_2e)
Mass Distance	=	Mass of sulphur multiplied by the distance shipped from sulphur manufacturing facility to pre-cast manufacturing facility (t km)
$EF_{Transport}$	=	Emissions factor for transportation of sulfur (kg CO_2e/t km)

The emissions due to the production and transportation of modifier are calculated as follows:

$$PE_{Modifier} = (M_{Modifier} \times EF_{Modifier}) + (Mass\ Distance_{Modifier} \times EF_{Transport}) \quad (10)$$

Where:

$PE_{Modifier}$	=	Emissions due to the production and transportation of the sulphur modifier (kg CO_2e)
$M_{Modifier}$	=	Mass of modifier used (t)
$EF_{Modifier}$	=	Emission factor for modifier production (kg CO_2e/t)
$Mass\ Distance_{Modifier}$	=	Mass of modifier and the distance shipped from modifier manufacturing facility to facility where modifier is added to sulphur (t km)
$EF_{Transport}$	=	Emissions factor for truck transportation (kg CO_2e/ t km)

The emissions due to electricity generation for operating the sulphur concrete facility are calculated as follows:

$$PE_{Electricity} = Electricity_P \times EF_{\ Elec} \quad (11)$$

Where:

$PE_{Electricity}$	=	Emissions due to the generation of electricity for use in the precast sulphur concrete facility (kg CO_2e)
$Electricity_P$	=	Electricity used in operating the sulphur concrete facility (kWh)
EF_{Elec}	=	Emissions factor for electricity (kg CO_2e/kWh)

8.3 Leakage

No sources of leakage have been identified for this project activity.

8.4 Summary of GHG Emission Reduction and/or Removals

The emission reductions for this project activity are calculated as follows:

$$ER_y = BE_y - PE_y \quad (12)$$

Where:

ER_Y	=	Net GHG emissions reductions and/or removals in year y
BE_Y	=	Baseline emissions in year y
PE_y	=	Project emissions in year y

9 MONITORING

9.1 Data and Parameters Available at Validation

The data specified below must be made available at validation by the project proponent. Default values may vary according the physical location of the project activity. The project proponent must provide evidence and justification that the values presented here are applicable to the project activity, or provide and justify project-specific values as needed.

Should the data parameters listed below not be available at the time of validation, the project proponent must provide a plan for determination and/or monitoring the data during the project. All parameters used must be reviewed on an annual basis to ensure the most current value is used in calculations.

Data / Parameter	$EF_{Portland\ Cement\ Production}$
Data unit	kg CO_2e/t
Description	Emission factor for the production of Portland cement
Equations	2
Source of data	Calculation using site specific data if available, or reference values if no site specific data is available
Value applied	
Justification of choice of data or	The pThe project proponent mustmay use site-specific

description of measurement methods and procedures applied	emission factors for accuracy if a specific facility factor can be justified for the baseline cement production facility. Reference values may be calculated if site specific information is not available using data published by the World Business Council for Sustainable Development based on region. See Appendix A for guidance. The project proponent must justify that the $EF_{Portland\ Cement\ Production}$ in Appendix A is conservative for the project.
Purpose of data	Calculation of baseline emissions
Comment	Aggregation of multiple product types may specify a method to determine this parameter for each product type rather than specifying a value for all product types included in the aggregation at the time of validation. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter:	EF Fuel
Data unit	kg (CO_2, CH_4, N_2O) per L, m3 or other of each type of fuel used
Description	Emissions factors for fuel combustion
Equations	6, 7 and 8
Source of data	Estimation; reference values must be obtained from regional, national, or international GHG inventories. In the absence of local or regional data, reference values may be obtained from the most recent version of the IPCC guidelines for national GHG inventories.
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	National emissions factors, or emissions factors created by local industry using internationally accepted procedures mustmay be used preferentially. Regional emissions factors may be used if national or local emissions factors are unavailable. International emissions factors may be used if regional emissions factors are unavailable. In the absence of local or regional data, reference values must be obtained from the most recent version of the IPCC guidelines for national GHG inventories.
Purpose of data	Calculation of project emissions

Comment	Review best practice guidance and accepted standards. Reference values are generally available. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter:	M_{CO2}
Data unit	kg/mol
Description	Molar mass of carbon dioxide
Equations	6
Source of data	General Chemistry book, 9th Edition, Ebbing & Gammon
Value applied	0.04401
Justification of choice of data or description of measurement methods and procedures applied	N/A
Purpose of data	Calculation of project emissions
Comment	This parameter is not likely to become out of date.

Data / Parameter	V_{STP}
Data unit	m^3
Description	Volume of one kg-mole of an ideal gas at standard temperature and pressure
Equations	6
Source of data	General Chemistry book, 9th Edition, Ebbing & Gammon
Value applied	23.6449
Justification of choice of data or description of measurement methods and procedures applied	The standard temperature and pressure conditions are 15°C and 101.325 kPa.
Purpose of data	Calculation of project emissions
Comment	This parameter is not likely to become out of date.

Data / Parameter	$Mass_{clinker}$ / $Mass_{Cement}$
Data unit	Percent

Description	Ratio of clinker to cement
Equations	3
Source of data	Site specific data, or reference values
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	The project proponent mustuse site-specific factors for accuracy if a specific facility can be justified for the baseline cement production facility. Reference values may be calculated using data published by the World Business Council for Sustainable Development based on region. See Appendix A for guidance. If site-specific factors are used, the project proponent must justify that the values are conservative for the project, and uncertainty is tracked where possible. The project proponent must also justify that the $EF_{Portland\ Cement\ Production}$ in Appendix A is conservative for the project.
Purpose of data	Calculation of baseline emissions
Comment	The project proponent must provide justification for factor used based on the region, kiln type and / or baseline facility records. Aggregation of multiple product types may specify a method to determine this parameter for each product type rather than specifying a value for all product types included in the aggregation at the time of validation. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	$EF_{Clinker}$
Data unit	kg CO_2e per tonne of clinker
Description	Emission factor for the production of clinker
Equations	3
Source of data	Site specific values as provided by the project proponent records, or reference values, such as those found in the World Business Council for Sustainable Development, Cement Industry Energy and CO2 Performance "Getting the Numbers Right" report.
Value applied	
Justification of choice of data or description of measurement	Proponents must use site-specific emission factors for accuracy if a specific facility can be justified for the baseline

methods and procedures applied	cement production facility. Reference values may be calculated, using data published by the World Business Council for Sustainable Development based on region. See Appendix A for guidance. The project proponent must justify that the $EF_{Portland\ Cement\ Production}$ in Appendix A is conservative for the project.
Purpose of data	Calculation of baseline emissions
Comment	The project proponent must provide justification for factor used based on the region, kiln type, fuel type and / or baseline facility records. Aggregation of multiple product types may specify a method to determine this parameter for each product type rather than specifying a value for all product types included in the aggregation at the time of validation. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	EF_{Elec}
Data unit	kg CO_2e per kWh
Description	Emissions factor for electricity
Equations	4 and 11
Source of data	Estimation; local or regional grid factors are preferable. If local factors are unavailable, reference values may be obtained from national and international GHG inventories may be used. In the absence of national data, reference values may be obtained from the most recent version of the IPCC guidelines for national GHG inventories. The value used must be consistent with the source of generation.
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Review of best practice guidance and accepted standards. Reference values are generally available for each regional grid.
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	The project proponent must ensure that the default value is representative of the type and source of elecricity used in the project. Default values must be sourced from recognized, credible sources and be geographically and

	temporally relevant to project specifics. This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	Electricity $_B$
Data unit	kWh
Description	Electricity used for operating the precast concrete facility
Equations	4
Source of data	Estimation based on historical data from electrical meter
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Metering of electricity may be direct or by a utility provider. Measurement mustbe continuous, with monthly aggregation (totalized).
Purpose of data	Calculation of baseline emissions
Comment	This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter	$EF_{Transport}$
Data unit	kg CO_2e/t km
Description	Emissions factor for transportation
Equations	9 and 10
Source of data	Fleet data (such as fleet-wide average emissions per distance), or default data may be used if fleet data is unavailable.
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	An emissions factor developed using internationally accepted practices may be generated for a fleet of vehicles, representing actual emissions due to fuel consumption per distance. If not available, regional data must be used and, in its absence, IPCC defaults may be used from the most recent version of IPCC Guidelines for national GHG inventories.
Purpose of data	Calculation of project emissions
Comment	Proponents may propose a fleet-specific emissions factor if

	sufficient documentation is available. The emissions factor must be reviewed at each verification period if actual fuel consumption is used in the emissions factor calculation. If retained shipping manifests, copies of shipping logs, or invoices from the supplier are used for the calculation, the resulting emissions factor must be cross checked against national or regional transport or fleet emission factors. If a default value is used, proponents mustjustify that it is conservative.

Data / Parameter	MF_{CO2}
Data unit	%
Description	Molar fraction of carbon dioxide in incinerated vent gas
Equations	8
Source of data	Facility-specific theoretical values are obtained from computer modeling or simulation, or through trial applications.
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Continuous measurement of this parameter is not economically feasible and estimation must provide an accurate value, as this parameter is not likely to vary significantly over the project life.
Purpose of data	Calculation of project emissions
Comment	This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

9.2 Data and Parameters Monitored

The data parameters specified below must be monitored during the project.

Data / Parameter:	$Mass_{Precast}$
Data unit	Tonne
Description	Mass of precast products produced
Equations	2
Source of data	Measurement or calculation.
Description of measurement methods and procedures to be applied	The mass of finished products may be measured, or if measurement not feasible, the mass could be calculated based on a material balance, or could be calculated based

	on design specifications.
Frequency of monitoring or recording	Per product type
QA/QC procedures to be applied	If a measurement approach is used, then regular calibration and maintenance of scales as per requirements of meter manufacturers ensures quality weight measurements.
Purpose of data	Calculation of baseline emission
Calculation method	N/A
Comment	Aggregation of multiple product types may specify a method to determine this parameter for each product type rather than specifying a value for all product types included in the aggregation at the time of validation.

Data / Parameter	$\%_{PC}$
Data unit	Unitless
Description	Ratio of Portland cement in finished product
Equation	3
Source of data	Estimated based on design criteria of product
Description of measurement methods and procedures to be applied	This percentage represents the amount of Portland cement that would have been contained within the finished product (in the baseline) compared to other components such as aggregate, water. Design criteria must be justified based on technical specifications or performance requirements of the product. Historical production specifications may also be used for justification of design criteria. This is a unitless value.
Frequency of monitoring/recording	Per product
QA/QC procedures to be applied	This parameter varies in the project scenario and must be monitored for each product but is not actually measured. Design specifications are sufficient to ensure accuracy on this parameter.
Purpose of data	Calculation of baseline emission
Calculation method	N/A
Comment	The use of manufacturer's specifications provides a method for establishing functional equivalence between the product used in the baseline scenario and the product used in the project scenario. Aggregation of multiple product types may

	specify a method to determine this parameter for each product type rather than specifying a value for all product types included in the aggregation at the time of validation.

Data / Parameter	Vol Fuel
Data unit	L, m^3 or other
Description	Volume of fuel combusted during the project
Equations	6
Source of data	Measurement of volume of fuel used.
Description of measurement methods and procedures to be applied	The project proponent may measure the volume of fuel consumed in one of two ways: 1. Direct metering or reconciliation of volumes received and in storage; 2. Reconciliation of volume of fuel purchased within a given time period.
Frequency of monitoring/recording	Monthly
QA/QC procedures to be applied	Regular calibration and maintenance of meters as per requirements of meter manufacturers ensures quality metering. Cross-checking of metered or purchased volumes compared to theoretical fuel use must occur at each verification period. Minor variations must be immaterial on a quarterly or annual basis. Long term trends must align with theoretical expectations and remain consistent on a per volume of product basis.
Purpose of data	Calculation of project emission
Calculation method	N/A
Comment	None

Data / Parameter	Mass Distance
Data unit	t km
Description	Mass distance of sulphur transported to the concrete facility
Equations	9
Source of data	Measurement of mass of sulphur received and distance the sulphur traveled.

Description of measurement methods and procedures to be applied	Direct measurement of mass of sulphur received and distance traveled based on manifests or supplier invoices.
Frequency of monitoring/recording	Each shipment
QA/QC procedures to be applied	Regular calibration and maintenance of scales as per requirements of meter manufacturers ensures quality weight measurements. Retention of shipping manifests, copies of shipping logs, or invoices from the supplier must be cross checked against processed volumes and distances estimated based on shipping routes. Minor variations must be immaterial on a quarterly or annual basis.
Purpose of data	Calculation of project emission
Calculation method	N/A
Comment	None

Data / Parameter	$M_{Modifier}$
Data unit	t
Description	Mass of modifier used in sulphur cement
Equations	10
Source of data	Measurement of mass of sulphur modifier
Description of measurement methods and procedures to be applied	Direct measurement of mass of modifier used in the concrete facility.
Frequency of monitoring/recording	Per shipment of modifier
QA/QC procedures to be applied	Regular calibration and maintenance as per requirements of meter/scale manufacturers ensures quality metering. Mass balance of all product constituents must align with metered values and provide a suitable confirmation that measurement equipment is providing accurate information between calibration intervals. Minor variations must be immaterial on a quarterly or annual basis.
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comment	None

Data / Parameter	$EF_{Modifier}$
Data unit	kg CO_2e/ t
Description	Emissions factor for modifier production
Equations	10
Source of data	Estimated based on manufacturer's specifications, fuel used, and electricity used.
Description of measurement methods and procedures to be applied	Value provided by the modifier manufacturer based on fuel and electricity consumed.
Frequency of monitoring/recording	Per shipment of modifier, to be updated annually by manufacturer of modifier
QA/QC procedures to be applied	Compare to historical values and analyze trends to confirm the estimate for emission factor is within a realistic range. Cross reference with manufacturer utility invoices for energy consumption to also ensure accuracy on estimate.
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comment	None

Data / Parameter	Mass $Distance_{Modifier}$
Data unit	t km
Description	Mass distance of modifier transported to the concrete facility
Equations	10
Source of data	Measurement of mass of modifier received and the distance the modifier traveled.
Description of measurement methods and procedures to be applied	Direct measurement of mass of modifier received and distance traveled based on manifests or supplier invoices.
Frequency of monitoring/recording	Each shipment
QA/QC procedures to be applied	Regular calibration and maintenance of scales as per requirements of meter manufacturers ensures quality weight measurements. Retention of shipping manifests, copies of shipping logs, or invoices from the supplier must be cross checked against processed volumes and distances estimated based on shipping routes. Minor variations must be immaterial on a quarterly or annual basis.

Purpose of data	Calculation of project emissions
Calculation method	N/A
Comment	None

Data / Parameter	$Electricity_{P}$
Data unit	kWh
Description	Electricity used for sulphur concrete facility in the project
Equations	11
Source of data	Measurement
Description of measurement methods and procedures to be applied	Metering of electricity may be direct or by a utility provider. Measurement must be continuous, with monthly aggregation.
Frequency of monitoring/recording	Continuously aggregated (totalized) per project with monthly reconciliation if project duration is longer than one month.
QA/QC procedures to be applied	Electricity utility standard maintenance and calibration procedures apply. Cross-checking of metered values versus engineering estimates or theoretical electricity usage values ensures accuracy between calibration intervals.
Purpose of data	Calculation of project emission
Calculation method	N/A
`Comment	None

Data / Parameter	$Vol_{vent\ gas}$
Data unit	m^3
Description	Volume of degassing vent gas incinerated
Equations	6
Source of data	Measurement of the volume of vented gas (direct metering), or default value.
Description of measurement methods and procedures to be applied	Direct metering of vent gas to the incinerator, or regional or sector-wide default values (in order of preference).
Frequency of monitoring/recording	Continuously aggregated (totalized) per project with monthly reconciliation if project duration is longer than one month.
QA/QC procedures to be applied	Regular calibration for direct metering method as per requirements of meters ensures quality metering. Intermittently cross reference metered value with theoretical

	volume to periodically confirm accuracy. Minor variations must be immaterial on a quarterly or annual basis.
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comment	Proponents must justify that the default value used for incinerator emissions is conservative.

9.3 Description of the Monitoring Plan

The project proponent must develop a monitoring plan detailing the procedures for data capture, measurement and reporting of the data parameters listed in Section 9.2. In general, data quality management must include sufficient data capture such that the mass and energy balances may be easily performed with the need for minimal assumptions and use of contingency procedures. The data must be of sufficient quality to fulfill the quantification requirement and be substantiated by company records for the purpose of verification.

The project proponent must establish and apply quality management procedures to manage data and information. Written procedures must be established for each measurement task outlining responsibility, timing and record location requirements. The greater the rigour of the management system for the data, the more easily an audit will be conducted for the project.

The project proponent must ensure that all documents and records are kept in a secure and retrievable manner for at least two years after the end of the project crediting period. Record keeping practices must be established that include:

- Electronic recording of values of logged primary parameters for each measurement interval;
- Written logs of operations and maintenance of the project system including notation of all shut-downs, start-ups and process adjustments relevant to the project quantification;
- Retention of copies of logs and all logged data; and
- Keeping all records available for review by a verification body.

The project proponent must also develop a QA/QC plan to add confidence that all measurements and calculations have been made correctly. QA/QC measures that may be implemented include, but are not limited to:

- Protecting monitoring equipment (sealed meters and data loggers);
- Protecting records of monitored data (hard copy and electronic storage);
- Checking data integrity on a regular and periodic basis (manual assessment, comparing redundant metered data, and detection of outstanding data/records);
- Comparing current estimates with previous estimates as a ‘reality check’;
- Provide sufficient training to operators to perform maintenance and calibration of monitoring devices;

- Establish minimum experience and requirements for operators in charge of project and monitoring; and
- Performing recalculations to make sure no mathematical errors have been made.

In general, measurement inaccuracies are inherently addressed in this methodology because the inputs into concrete production are measured or metered to ensure that concrete mix specifications are met. Therefore, there is a high degree of certainty in the measurements of associated with sulphur, aggregate, modifier, and volumes of fuel employed. However, the project proponent must address uncertainties in all measured values for all quantification parameters by ensuring that meters or scales are appropriately calibrated as prescribed by the manufacturer.

Parameters relevant to the project quantification for which confidence intervals may possibly be generated include MF_{CO2} and $Mass_{precast}$. If a direct measurement approach is employed (such as sampling the population of finished precast products in the case of $Mass_{precast}$, or trial application sampling in the case of MF_{CO2}) then a confidence interval must be determined. If the 95% confidence limits fall outside of 15% of the calculated value (as per the CDM Methodology Panel guidance), then a confidence deduction must be applied, using conservative factors such as those specified in the CDM Meth Panel guidance on addressing uncertainty in its Thirty Second Meeting Report, Annex 14.

In the situation where a computer simulation, mass balance process, or design specifications is used as a source of data (for either MF_{CO2} or $Mass_{precast}$), the uncertainty associated with each input to the simulation, or design process must be determined. If the resulting uncertainty of the simulation output falls outside of 15% of the calculated value, a confidence deduction must be applied, using conservative factors, as above. Similarly, if site-specific factors for $Mass_{clinker}$ / $Mass_{Cement}$ are employed and uncertainty is tracked, and if the resulting uncertainty falls outside of 15% of the calculated value, then a confidence deduction must be applied, using conservative factors, as above.

Parameters relevant to the project quantification for which confidence intervals cannot easily be generated include those listed below. The project proponent must demonstrate the factors or values used in the project are appropriately conservative based on the uncertainty of the actual parameter during the project.

- $Vol_{\text{vent gas}}$
- $EF_{\text{Portland Cement Production}}$
- $EF_{\text{Fuel i}}$
- $Mass_{clinker}$ / $Mass_{cement}$
- $EF_{clinker}$
- $EF_{Transport}$

- Ratio of Portland cement in finished product ($\%_{PC}$)
- $Vol_{Fuel\ i,\ DG,\ AH}$
- Mass distance of sulphur transported to the concrete facility
- $M_{modifier}$
- $EF_{modifier}$
- Mass distance of modifier transported to the concrete facility
- $EF_{Electricity}$
- $Electricity_B$
- $Electricity_P$

Methods used by the the project proponent for estimating uncertainty must be based on recognized statistical approaches such as those described in the *IPCC Good Practice Guidance and Uncertainty Management in National Greenhouse Gas Inventories*. Where applicable, confidence deductions applied must use conservative factors such as those specified in the CDM Methodology Panel guidance on addressing uncertainty in its Thirty Second Meeting Report, Annex 14.

APPENDIX A: EMISSIONS FACTORS FOR THE PRODUCTION OF PORTLAND CEMENT

This section discusses the emissions factors for the parameter $EF_{Portland\ Cement\ Production}$.

Specific Displacement

The mass of sulphur cement produced by the project may displace Portland cement from a specific Portland cement production facility. Provided the project proponent can demonstrate and justify specific displacement, site specific factors for kiln emission intensity and clinker to cement ratio must be used based on facility feedstock and fuel records.

In general, the equation for determining an emission factor based on site specific information is provided below:

$$EF_{Clinker} = \frac{\sum_k \left(Vol\ Fuel_k\ \times EF\ Fuel_{k,x}\ \times GWP_x\right)}{Mass_{Clinker}} + 540\ kg_{CO2}\ tonnes^{-1}$$

Where:

$EF_{clinker}$	=	Emission factor per tonne of clinker for the baseline scenario (kg CO_2e/t clinker)
$Vol\ Fuel_k$	=	Volume of each type of fuel combusted for clinker production (L, m^3 or other)
$EF\ Fuel_{k,x}$	=	Emissions factor for fuel combustion for each GHG listed (kg GHG/L, m^3 or other).
GWP_x	=	Global warming potential for each GHG (CO_2, CH_4, N_2O)
$Mass_{Clinker}$	=	Mass of total clinker production in the quantification period (t)
540 kg_{CO2} $tonnes^{-1}$	=	Mass of CO_2 attributable to the calcination of one tonne of clinker.

The amount of CO_2 released due to the calcination of one tonne of clinker has been described as nearly constant by the authors of the World Business Council for Sustainable Development in the report "Cement Industry Energy and CO_2 Performance: Getting the numbers right." This value is considered nearly constant. However, proponents may propose an alternative method to calculate the amount of CO_2 released due to the calcination of one tonne of clinker with justification.

The clinker to cement ratio (as described in Equation 3) is based on actual measurements of mass of cement produced and mass of clinker produced in the quantification period. It is expressed as a unit-less value (or percent) and applied as described in Equation 3.

Uncertainty related to the source of displaced Portland cement must be low and must be characterized by reviewing regional cement supply. Proponents must demonstrate that the distance/economics/logistics/etc. of secondary supplies of Portland cement would have not been viable.

Regional Displacement

The mass of sulphur cement produced by the project may displace Portland cement on a regional basis, meaning multiple Portland cement production facilities would contribute to the general cement supply in a region. In the absence of evidence for a specific displacement, the project proponent must demonstrate and justify regional estimates for kiln emission intensities and clinker to cement ratios. The project proponent must demonstrate that the factors used are conservative.

Regional factors may be determined by the project proponent and must be justified by citing records / studies / etc. specific to the region relevant to the project. In the absence of actual regional factors, an international report is cited below with reference to international regional kiln emission intensities and clinker to cement ratios.

The emission factor for clinker production and the ratio of clinker in Portland cement are listed below in Tables A1 and A2, respectively and were derived from the World Business Council for Sustainable Development's the Cement Sustainability Initiative report, *Cement Industry Energy and* CO_2 *Performance "Getting the Numbers Right"*.

The factors in Table A1 include emissions from the chemical process of calcination and emissions from fuel combustion, and consider those facilities that combust a wide range of carbon intensive and biogenic fuel sources.

Table A1: CO_2 emissions per tonne of clinker per kiln type (global average)

Kiln Type	kg CO_2/tonne clinker ($EF_{Clinker}$)
Dry with preheater and precalciner	842
Dry with preheater and without precalciner	861
Dry without preheater	955
Semi wet/Semi dry	896
Wet	1043

Table A2: Ratio of Clinker to Cement on a Regional Basis

Region	Clinker to Cement Ratio (%)
Africa and Middle East	79
Asia excluding China, India, CIS and Japan	84
China and India	74
CIS	80
Europe	76
Japan, Australia and New Zealand	83

Latin America	74
North America	84
World	78

The project proponent must justify the above factors are conservative to determine the emission factor for production of Portland cement in the absence of justification of site specific or region specific factors. This ensures uncertainty in the estimates is accounted conservatively.

2 SUMMARY DESCRIPTION OF THE METHODOLOGY

Additionality and Crediting Method	
Additionality	Project Method
Crediting Baseline	Project Method

2.1 Project Activities

The project activities eligible to apply this methodology include any that manipulate number and type of domestic livestock grazing animals (e,g cattle, sheep, horses, goats, camels, llamas, alpacas, guanacos, or buffalo) and/or grouping, timing and season of grazing (eg, continuous unrestricted, planned rotational, bunched herd rotational or other means of restricting livestock access to forage in order to allow vegetation response) in ways that sequester soil carbon and/or reduce methane emissions. Altering fire frequency and/or intensity, (eg, shifting from late season to early season burning or changing prescribed burn schedules from one every other year to one every five years) in ways that increase carbon inputs to soil, is also an included activity. Increased fire may be used to shift plant species composition such that net carbon sequestration in soil increases (eg, conducting a single burn to shift vegetation from shrubs to grasses), but the net increase in SOC must compensate for any losses in woody biomass and increases in methane (CH_4) and nitrous oxide (N_2O) emissions. Grassland restoration activities to improve livestock forage density (eg seeding of legumes or perennial grasses) that do not involve mechanical tillage of soil are allowed.

It is expected that such project activities will occur on grasslands that have historically experienced SOC loss. As these areas would continue to maintain low levels or further loss of SOC in the absence of the project, it is therefore expected that other carbon pools, such as aboveground carbon pools or biomass, will have relatively little change. The loss of SOC in the baseline prior to the project start date may be caused by fires that occur frequently enough to reduce SOC, or overgrazing that is expected to continue in the absence of the project.

Some grasslands (eg, savannas and open woodlands) may feature significant aboveground woody plant biomass that exceeds five percent of the soil carbon pool. Some woody biomass, largely in the form of shrubs or small trees, can reduce grass density and soil carbon. Management fires to reduce this woody cover might therefore reduce carbon in the aboveground woody biomass pool but compensate by increasing grass production and total carbon sequestration in soil.[1] Such scenarios are allowable under this methodology.

2.2 Quantification Approach

Projects may rely on measured or modeled approaches (see Table 1 below):

Measured approach: Emission reductions are quantified following a period in which enhanced soil sequestration and/or reduced methane emissions can be demonstrated. Such projects have a reduced uncertainty compared to those following a modeled approach, but projects that include soil sequestration activities may claim and verify emission reductions only after increases in soil carbon can be detected (likely every five or more years, depending on the productivity of the site).

Modeled approach: Emission reductions are quantified using a validated model after demonstrating management activities, which are known to sequester carbon and/or reduce methane emissions, have been implemented. Reduced emissions from sequestration and reduced methane emissions associated with these activities are then estimated by models with acceptable precision which have been validated for the project and re-calibrated at regular intervals thereafter (5-10 years, depending on the productivity of the site).

Modeled approaches have higher uncertainty due to the uncertainty in the parameters used to calculate emissions and removals and the uncertainty in whether model calculations actually describe changes in sequestration and reduced emissions. Consequently, verified modeled emission reductions will likely be reduced due to uncertainty deductions. However, because activities may be demonstrated annually, emission reductions may be verified annually, if desired.

This modeling approach requires the use of soil carbon models that have been published in peer-reviewed journal articles. Models must have been validated with independent data. Data used to validate the model must have been published in a peer-reviewed journal article and independent from data used to build the model. Soil carbon models describe how the density of soil organic carbon (SOC) changes as a result of biogeochemical processes and soil characteristics (eg, soil texture and type, pH, temperature, and moisture) and modifications in the capture of CO_2 and production of carbon-containing root and shoot biomass by plants. This aboveground and belowground biomass may undergo one of several fates:

1) Conversion back to CO_2 by combustion during fire,
2) Consumption and respiration by grazing animals,
3) Decomposition and respiration by microbes in soil and/or in the guts of invertebrate decomposers, or
4) Remaining as SOC from decomposed plant material or grazing animal dung.

As would be expected for such a complicated process, such models usually require the input of many parameters that need to be measured or obtained from the literature. When choosing which approach to take, the project proponent must consider carefully its ability to obtain necessary parameter measurements and to validate the chosen model for their project area.

Table 1: Summary of Measured vs Modeled Approaches

Measured Approach	Frequency	Modeled Approach	Frequency
Baseline			
Demonstration of SOC impoverishing activities		**Demonstration of SOC impoverishing activities**	
Measurements		**Measurements**	
* Initial SOC		* Initial SOC	
* Past grazing animal numbers		* Past grazing animal numbers	
* Forage quality		* Forage quality	
* Uncertainty analysis		* Past fire frequency	
		Build Model	
		* Choose model	
		* Measure/find parameters	
		* Accuracy assessment of prediction	
		* Predict initial SOC	
		* Monte Carlo analysis for uncertainty	
Project Scenario			
* Conduct activities * Measure ΔSOC * Animal numbers during crediting period * Forage quality during crediting period * Uncertainty analysis	Every 5-10 years	* Conduct activities * Measure/find parameters * Measure project fire frequency * Measure grazing animal numbers * Calculate methane emissions * Uncertainty analysis	Every 1-2 years
Verified Carbon Unit Calculation at Verification			
* Methane * Uncertainty analysis and deduction ***Claim VCU's**	Every 5-10 years	* Calculate ΔSOC from model * Methane * Uncertainty analysis *** Claim VCU's**	Every 1-2 years
Model Re-calibration			
		* Measure/find parameters * Measure ΔSOC * Assessment of prediction * Model adjustment	Every 5-10 years

Table 1 summarizes the procedures for applying either the measured approach or the modeled approach. While there are additional steps to using the modeled approach compared to the measured approach, the project proponent may monitor activities and calculate emission reductions more frequently (eg every 1-2 years as opposed to every 5-10 years) with the measured approach.

2.3 Baseline and Project Emissions and Reductions

The project proponent must demonstrate baseline conditions for the 10 years prior to the project start date, including:

1) land uses,

2) fire histories such as the number of times, sections or strata of the project area burned and when these fires occurred, and

3) grazing livestock animal numbers from detailed records such as surveys of livestock owners, past aerial surveys or ground censuses of livestock animals. These data are necessary to assess baseline methane emissions from enteric fermentation.

Baseline conditions may be determined from analysis of past satellite images, such as MODIS Burned Area Product maps to assess fire histories or with other satellite imagery such as Landsat, with demonstrated suitability from peer-reviewed scientific papers and/or from data from the project area to detect vegetation types and trends. Interpretation of satellite images during the project crediting period coupled with ground assessments of the occurrence of fire at multiple sampling stations is needed for verification of fire-abatement activities.

For the project scenario, both the modeled and measured approaches require sampling of soils and measurement of bulk density and SOC. If using the modeled approach, the soil sample depth is determined by the model (eg, 20 – 100 cm). This sampling will occur at the start of the project and be used to establish the baseline scenario. Likewise, for both approaches, ground censuses, household surveys, and/or aerial surveys of grazing animal numbers broken out by species, sex, and age are needed to determine baseline methane emissions and project reductions (or increases).

The measured approach simply calculates the difference in SOC at each verification event since the project start date or previous verification event. Note that sufficient time must pass between verification events to detect changes in SOC (eg, five or more years, depending on productivity in the project area). The initial and subsequent measurements of SOC occur at each of many permanent sampling stations located in different subareas (strata) within the project area that differ strongly in current or past vegetation, soil types or management activities. The sum of the differences in SOC, called ΔSOC, at each sampling station across the project area reflects net GHG emission reductions and removals from the soil carbon pool.

If a modeled approach is used, measurements of parameters, or information used to obtain parameter values, must be available to be input into a peer-reviewed, published, and accuracy-tested (at least once) model of soil carbon dynamics (eg, SNAP[2] CENTURY[3, 4]], EPIC[4], or the Hurley Pasture[5] models). The model must include parameters impacted by project activities (eg, grazing intensity and fire frequency) as well as critical factors affecting carbon inputs and outputs to soil (eg, soil texture, climate, and plant characteristics that affect decomposition). The specific factors needed will depend on the model used, as some models, such as CENTURY, require more than 20 factors, while others, like SNAP, require only five factors. To ensure that a model predicts changes in emissions or removals accurately and precisely enough to achieve a sufficiently low uncertainty in estimated changes in carbon stocks from project activities, the chosen model must be tested to demonstrate it is appropriate for use in the project area. Such a test uses site condition and management history data to predict carbon stocks that reflect the consequence of past management actions and conditions, such as rainfall, plant species composition, grazing intensity and fire history. This predicted carbon stock is compared to current, measured carbon stocks and the accuracy and precision of the predictions must be demonstrated within subareas (strata) of the project area that differ strongly in past conditions or in management activities. The details of the model test are presented in section 8.1.3.3.

Following the model test, soil carbon dynamics are modeled for the project area to estimate the maximum SOC that would likely have occurred for the 10 years prior to the project start date, as the baseline SOC. The same model is then used to calculate an expected future equilibrium SOC under proposed project activities, the time in years to reach this equilibrium, and the average annual increment in SOC sequestration expected under the proposed project activities. The statistics of variation needed to calculate uncertainties for each parameter in the model are also required in order to determine an overall uncertainty in the model calculations of SOC through a Monte Carlo simulation analysis. Uncertainty in the difference between maximum SOC in the past 10 years and an expected future equilibrium SOC will be used to determine any potential uncertainty deduction (section 8.4.4).

2.4 Leakage

Emissions from leakage primarily occur from the displacement of current activities inside the project area to areas outside the project area. For this proposed methodology, leakage would occur primarily by displacement of livestock to other grazing lands in which grazing would result in loss of soil carbon and/or increased methane emissions. Such displacement is limited by the applicability conditions for the methodology, but where displacement does occur leakage emissions must be quantified according to the procedures within the methodology.

3 DEFINITIONS

In addition to the definitions set out in VCS document *Program Definitions*, the following definitions and acronyms apply to this methodology:

3.1 Defined Terms

Baseline Period
A historical reference period over which the project's baseline emissions are calculated, and that consists of the ten consecutive years occurring immediately before the project start date

Calibration
Process by which predictive models use local measurements to determine the values of their parameters, and which will make the models more representative of the project area.

Calibration Period
Under a modeled approach, the time in years following the project start date or most recent re-calibration when soil carbon is to be measured again in order to re-calibrate the chosen soil carbon model. This period may be much longer than the verification period for modeled approach projects in order to allow sufficient time for measureable changes in soil carbon to occur

Cellulose
Carbon-rich plant material that, to decompose requires special enzymes (cellulases) typically found only in certain fungi, bacteria or other microorganisms

Enteric Fermentation
Process of microbial digestion of plant material in the digestive tract of grazing animals that, in the absence of oxygen, yields methane (CH_4) as a byproduct

Equilibrium
State of a carbon pool when inputs to the pool are balanced by outputs, such as when inputs to soil organic matter are balanced by losses from respiration by microorganisms

Exclosure
Fence or other device that excludes grazing animals from an area, sufficient to allow measurement of aboveground biomass inside in order to compare with biomass outside; used in estimating grazing intensity

Fire management
Set of practices that either inhibit fire or burn vegetation on purpose to achieve desired goals for vegetation and soil carbon.

Grasslands
Lands with more than 250 mm mean annual precipitation covered by natural and managed herbaceous cover that lack trees over 5m in height with greater than 50% canopy cover (forests)[1]

Grazing animal
Mammals that eat primarily herbaceous plants or the leaves of shrubs; in this methodology, applies to livestock species subject to control by the project proponent

Legumes
Plants in the pea family, either woody or non-woody, that harbor bacteria in their roots that perform nitrogen fixation, or the conversion of nitrogen gas in the atmosphere into chemical forms that can be used by plants

Lignin
Carbon-rich plant material that is generally impervious to decomposition by microorganisms

Neutral Detergent Fiber
Plant material resistant to rapid digestion or decomposition, which includes cellulose and lignin

[1] http://www.fao.org/agriculture/crops/thematic-sitemap/theme/spi/gcwg/definitions/en/

Overgrazing

Grazing that has resulted in permanent vegetation species changes from mostly palatable to unpalatable species, reduction in vegetation cover that expose more than 80 percent bare ground, and/or consumption of more than 75 percent of production

Prescribed Fires

Fires that are set on purpose by landholders as part of a specific strategy to manage vegetation in the project area

Rotational Grazing

Various practices of planned grazing in which animals are restricted, by herding or fencing, to small portions (< 25%) of available grazing lands for relatively short periods of time, followed by movement to new portions of available grazing land. The restricted access and time is designed for livestock grazing animals to eventually visit all or most of available grazing lands but still allow forage plant species sufficient time and resources (water, nutrients) to regrow and set seed following grazing or to complete growth and seed set before grazing.

Soil Organic Carbon Density

Amount of carbon in the soil, expressed as a mass per unit area rather than as a percent

Soil Carbon Dynamic Model

A model published in the peer-reviewed scientific literature that predicts changes in soil organic carbon as a function of various input variables, which may include aboveground production, belowground production, precipitation, temperature, initial soil organic carbon, soil texture, and grazing intensity and possibly other factors detailed in the peer-reviewed article(s) describing the model

Soil Organic Carbon (SOC)

See VCS document *Program Definitions*.

Tier 1, 2, or 3

The level of precision and use of local measurements in calculating various emissions and removals of greenhouse gases, as assigned by the IPCC

3.2 Acronyms

A/R	Afforestation / Reforestation
AFOLU	Agriculture, Forestry and Other Land Use
AIC	Akaike Information Criterion
ALM	Agricultural Land Management
CDM	Clean Development Mechanism
CI	Confidence Interval

IPCC	Intergovernmental Panel on Climate Change
NDVI	Normalized Difference Vegetation Index
SAVI	Soil-Adjusted Vegetation Index
SGMAFG	Sustainable grassland management though adjustment of fire and grazing
UNFCCC	United Nations Framework Convention on Climate Change
VCS	Verified Carbon Standard
VCU	Verified Carbon Unit

4 APPLICABILITY CONDITIONS

This methodology applies to project activities that adjust the number, type and husbandry of grazing animals, adjust the frequency and intensity of planned or unplanned fires, and/or introduce herbaceous grassland species as potential forage for grazing animals or to restore degraded soils.

The methodology is applicable under the following conditions:

1) The project area must be grasslands in the baseline and project scenarios.
2) Lands are grazed and/or subject to fires in the baseline and/or project scenarios. Lands may be used for different purposes, such as livestock production, conservation, hunting or tourism.
3) The project must be structured to keep livestock within the project area, and the project proponent must be able to enforce the boundaries of the project area.
4) The project must result in no net increase in the density of, or time spent by animals in confined corrals where dung can pile up and begin to decompose anaerobically[5] and result in CH_4 and N_2O emissions, such as an increase in the number of livestock aggregated (eg, kept in corrals or pens) that would result in more than 50 percent of the ground area covered by dung.[2]
5) Baseline emissions derived from livelihood-driven human impacts on aboveground woody biomass (eg, cutting for fuel wood, charcoal or timber sales) must be deemed de minimis (ie, not included in the cumulative 95 percent of total baseline emissions) and project activities cannot significantly alter such livelihood-driven activities.
6) For projects that propose to modify grazing, the maximum individual project size[3] is 3 million ha or 5 percent of a country's land area currently or potentially used to graze livestock, as judged by national government land use inventories or other documentation.

[2] This criterion is conservative relative to the conditions of dung accumulation that would result in significant anaerobic decomposition

[3] These constraints are designed to avoid market leakage, such as if a reduction in livestock created a meat or milk shortage that would encourage overstocking of livestock elsewhere in a country

The methodology is not applicable under the following conditions:

- Project activities that involve mechanical vegetation removal or soil tillage
- The project area receives a net import of inorganic or organically-derived fertilizer

5 PROJECT BOUNDARY

The spatial extent of the project boundary must be established following the guidelines in the latest version of the VCS document *AFOLU Requirements*.

Table and 3 below identify the carbon pools and GHG sources included or excluded from the project boundary.

Table 2: Selected Carbon Pools under Baseline and Project Activity

Carbon Pools	Included?	Justification/ Explanation
Aboveground woody biomass	Optional	Where the project activities involve changes in fire management, the project proponent must monitor changes in aboveground woody plant biomass. Where the project activity is to reduce fire frequency, there may be increases in removals from woody biomass which must be quantified and monitored. Where the project plans to burn woody biomass to promote soil sequestration, aboveground woody biomass must be included, because woody plants in some savanna grasslands can account for 10-30 percent of carbon stocks[6] and can be dramatically reduced by fire. Where the project activities do not involve changes in fire management, quantification and monitoring of changes in removals from woody plant biomass is optional.
Aboveground non-woody biomass	No	Aboveground non-woody biomass is typically burned or decomposed within the same year of its production and therefore is not a major sink and is considered in balance with CO_2 uptake, respiration by plants, and annual decomposition[7]
Belowground biomass	No	Belowground non-woody biomass is typically burned or decomposed within the same year of its production and therefore is not considered a major sink in grasslands because it is considered in balance with CO_2 uptake, respiration by plants, and annual decomposition [7]. As tillage is not allowed according to applicability conditions, any increase from project activities may be conservatively excluded.
Dead wood	No	Negligible in grasslands, particularly those with fire.
Litter	No	In grasslands, litter exhibits high turnover which further reflects balance with CO_2 uptake, respiration by plants, and annual decomposition[7].
Soil organic carbon (SOC)	Yes	Major carbon pool covered by SGMAFG
Wood products	No	An optional pool for VCS ALM projects, it is considered negligible for untilled grasslands

This methodology has applicability conditions for no tillage and activities that do not include avoided conversion of grasslands. Consequently, aboveground non-woody biomass, litter, and belowground biomass are considered negligible sinks because they turnover considerably throughout the year, sometimes by as much as 100 percent [7]. These carbon pools may later be used as potential parameters for soil carbon models because they influence the input of carbon to the soil, but they do not represent significant, permanent sinks or reservoirs of carbon.

Table 3: GHG Sources Included In or Excluded From the Project Boundary

Source		Gas	Included?	Justification/Explanation
Baseline	Grazing animals	CO_2	No	Balanced with CO_2 uptake, respiration by plants, and annual decomposition [7]
		CH_4	Yes	Target removal for methodology
		N_2O	No	No increase in concentration of dung and forage if not fertilized (see applicability conditions)
	Burning biomass	CO_2	No	Balanced with CO_2 uptake by plants
		CH_4	Optional	If reducing or maintaining fire is a project activity, CH_4 may be conservatively excluded. Otherwise CH_4 emissions must be calculated to determine net change in carbon stocks from increasing fire to induce an increase in SOC
		N_2O	No	Negligible under applicability conditions
	Soil emissions	CO_2	No	Assumed to be in balance with C inputs to SOC (SOC at equilibrium)
		CH_4	No	Negligible since project is not in wetland
		N_2O	No	Negligible under applicability conditions
Project	Grazing animals	CO_2	No	Balanced with CO_2 uptake by plants
		CH_4	Yes	Target removal for methodology
		N_2O	No	No increase in concentration of dung (applicability conditions) and forage is low in N
	Burning biomass	CO_2	No	Balanced with CO_2 uptake by plants[7]
		CH_4	Optional	If reducing or maintaining fire is a project activity, may be conservatively excluded. Otherwise CH_4 emissions must be calculated to determine net change in carbon stocks from increasing fire to induce an increase in SOC
		N_2O	No	Negligible under applicability conditions
	Soil emissions	CO_2	No	Accounted for in measured ΔSOC
		CH_4	No	Negligible since project not in wetland
		N_2O	No	Negligible under applicability conditions

Unless specifically planted at high density to achieve aboveground biomass greater than 120 g/m^2 on average, leguminous plants, either woody (eg, *Acacia* or *Prosopis* species) or herbaceous, are not likely to produce soil N_2O emissions to levels that approach 5 percent of total CO_2 emissions from soil [8, 9]. Consequently, N_2O emissions from soil or biomass burning are negligible.

As per applicability condition 4, this methodology does not apply to projects that result in a net increase in the density of, or time spent by, animals in confined corrals where dung can pile up and begin to decompose anaerobically[5] and result in CH_4 and N_2O emissions. Dung in pastures or open rangelands typically decompose aerobically [10, 11], which releases negligible CH_4 and N_2O emissions.

Increase in the use of fossil fuels due to management, harvesting, and fighting fires is likely to be negligible because the same general activities (eg, livestock grazing, wildlife conservation and tourism) will be occurring in the project area during the project lifetime as under baseline conditions.

6 BASELINE SCENARIO

The baseline scenario is identified as the existing or historical land management practices, under the assumption that these would continue in the absence of the project. The baseline land management activities, such as plans (or lack thereof) for fire management, number of grazing animals and the duration and timing of grazing particular areas of land, must have been in place during the baseline period. In the case that management activities have changed during the baseline period, such changes must be documented and the activities leading to the lowest net emissions or greatest removals during the baseline period must be chosen as the most plausible baseline scenario.

To develop the baseline scenario, the project proponent must document, using published or gathered project-specific data and/or models, historic grazing plans or use of grazing areas by livestock and fire histories in the project area. The method to determine the most plausible baseline condition is provided in Section 8 (Baseline Emissions) with additional information provided in Section 9.3 (Description of the Monitoring Plan). The method includes:

1) Where adjustments in fire frequency and/or intensity are a project activity, the project proponent must demonstrate a fire history, as a map of areas that burned and the number of times they burned over the previous ten years. This may be obtained by using satellite products, such as MODIS Burned Area Product[4] as detailed in Section 9.3.5) that provide polygons of burned areas for 15 day periods throughout the dry or burning season. A GIS program like Quantum GIS (2.6)[5], and other programs like IDRISI [6] or ArcGIS, may perform similar functions. Project proponents may also use dated aerial

[4] http://modis.gsfc.nasa.gov/)
[5] Quantum GIS 2.4 can be downloaded for free at https://www.qgis.org
[6] http://www.clarklabs.org

photographs or accurate hand-drawn maps accompanied by records of where and when land parcels burned.

2) As evidence of past grazing practices and impacts, the project proponent must demonstrate a grazing history, as determined from past livestock grazing animal counts, ground measurements of grazing impacts, and/or ground-validated interpretations of satellite imagery (such as the Normalized Difference Vegetation Index (NDVI), Soil-Adjusted Vegetation Index (SAVI), or other similar index[12, 13]) from a minimum of four intervals across the 10 years, with at least one image from 8-10 years prior to the project start date.

3) Baseline methane emissions require as detailed as possible livestock grazing animal censuses through any combination of professional aerial surveys, ground counts with appropriate spatial extrapolation to the project area[14, 15], or household surveys of livestock held by each household over the previous 10 years. Censuses must categorize, to the extent possible, the species, sex, and age of each animal, and an average body weight for each category[7].

4) Aboveground woody biomass must be sampled at the project start from many locations in the project area (see Section 8.1.3.5) and if necessary for inclusion as a parameter in soil carbon models, analyzed for neutral detergent fiber, cellulose, and lignin in a professional laboratory.

5) Initial soil carbon stocks must be measured to the desired depth following Section 8.1.3.3. The chosen depth must match that applicable to the chosen soil carbon model if the modeled approach is used.

6) Where the modeled approach is used, predictions of soil carbon stocks or stock changes from the chosen model of soil carbon dynamics, such as Century[3, 4, 16], must be tested to demonstrate it is appropriate for use in the project area with measured soil carbon stocks or stock changes from the project area. Correlations between predicted and observed stocks must have $R^2 \geq 0.80$ within strata and an uncertainty based on a 95 percent confidence interval of $\leq$ 20 percent for predicted values applicable to the project area. The use of less accurate model predictions imply larger confidence limits in estimated carbon stocks or stock change after 10 years and thus larger uncertainty deductions in claimed emission reductions. If a model cannot be found to provide sufficient accuracy, the measured approach must be used.

7) The selected model is used to model the soil carbon dynamics and to estimate the maximum SOC that would have occurred in the 10 years prior to the project start date. This provides an uncertainty deduction for activity-based emission reduction calculations.

---

[5] IPCC, *Emissions from livestock and dung management*, in *Guidelines for Nartional Greenhouse Gas Inventories*. 2006, IPCC. p. 1-85.

[7] Such data are necessary to use Tier II methods of calculating methane emissions per IPCC 2006 guidelines

8) Where the measured approach is used, estimates of initial soil carbon stocks within different strata must also calculate an uncertainty based on a 95 percent confidence interval, with uncertainty deductions imposed if uncertainty exceeds + 15 percent**.**

9) Uncertainty propagated by all estimated emissions and reductions must be calculated for baseline emissions, project emissions and reductions. Uncertainty deductions will occur if the total uncertainty + 15% percent of estimated net emissions and removals under the project scenario. The deducted removals must be directly proportional to the uncertainty.

7 ADDITIONALITY

Additionality must be demonstrated using the latest version of the VCS tool VT0001 *Tool for the Demonstration and Assessment of Additionality in VCS Agriculture, Forestry and Other Land Use (AFOLU) Project Activities*. In this tool, the project proponent must (1) identify alternative land use scenarios to the proposed project activity, (2) perform an investment analysis to determine that the proposed project activity is not the most economically or financially attractive of the identified land use scenarios or (3) identify key barriers, and (4) demonstrate how the proposed project activity deviates from common practice.

8 QUANTIFICATION OF GHG EMISSION REDUCTIONS AND REMOVALS

8.1 Baseline Emissions

8.1.1 Baseline Management Activities

The project proponent must document the management activities that occurred during the baseline period, in order to quantify baseline emissions and/or removals. Management activities must include:

1) The number of livestock grazing animals of different categories (eg, weight, sex, age and species) in one or more areas within or in the entire project area.

2) The average forage removal, or grazing intensity (%) by all animals, as measured by comparison of forage biomass inside and outside fenced exclosures[2, 17], or inside and outside unfenced areas otherwise avoided by livestock, such as conservation areas, with similar soil and climate, or before and after planned grazing events. Estimates of grazing intensity over large areas may be made by using satellite-based indices, such as NDVI[12, 13] , as long as such indices are correlated with ground measurements with a R^2 > 0.35.

3) The pattern of time and timing of animal use of the project area.

4) Prescribed burns at some desired frequency.

Management activities may also be considered to mean a lack of management in the form of unplanned livestock grazing, lack of grazing, or unplanned fires. The project proponent must also provide evidence of the baseline vegetation conditions and their association with management activities in the project area during the baseline period. Such evidence must take the form of any one or combination of the following, in no particular order of preference:

5) Field data on vegetation composition (biomass, percent cover, incidence). Dominant vegetation types that are associated with lower soil carbon (eg, annual plants) or with grasses with high lignin and cellulose content such as various *Pennisetum* spp. (in Africa), *Spinifex* spp., (Australia), switchgrass *Panicum virgatum* or Johnson grass *Sorghum halepense* (North America), or *Paspalum* spp. (South America)) following consumption by livestock. These data may be presented as visually estimated percent cover of different vegetation types and average percent cover of annual and perennial grasses, bare ground and shrubs, must be provided if applicable.

6) Measurements of grazing intensity from exclosure (fence) experiments, visual estimates calibrated from exclosure experiments or ungrazed areas within the project area with similar soils and rainfall to areas where soil carbon is expected to be increased.

7) GPS-referenced, dated photographs of a representative sample of the project area, with sufficient evidence to judge a shift to project scenario vegetation from similar photographs taken of the same view at the same GPS point.

8) Interpreted satellite images, such as indices of NDVI[12, 13] or maps of burned areas[18, 19] across multiple years, coupled with ground vegetation data to support the conclusion that these images are correctly interpreted with reasonable accuracy (ie, R^2 > 0.35 between index and vegetation measure from 1).

8.1.2 Design and Establishment of Permanent Sampling Stations

This methodology depends greatly on the success at measuring changes in SOC, the results of project activities, and/or key inputs into soil carbon models such as grazing intensity and/or the intensity and frequency of fires. Because these measurements in grasslands often vary by a large amount over distances of a few meters, the project proponent must establish permanent sampling stations, marked with permanent materials, like PVC, metal or stone, with recorded GPS locations to 10 meter accuracy, or close enough to find the permanent markers of the station. Measurements of carbon stocks in soil and wood (if relevant) at the same place may then be compared over time and control for initial differences in SOC, grazing and fire history, vegetation, topography, and other factors. Project impacts on carbon stocks are therefore best detected by measuring the change in carbon stocks between years at each sampling station and then summed over all sampling stations rather than the difference between mean stocks across all sampling stations in different years. This sampling approach will greatly reduce the variance, and therefore, uncertainty, in changes in stocks between baseline and project activities. Further details about measurements at these permanent stations are discussed in Section 0.

8.1.2.1 Number of Sampling Stations

The total number of sampling stations, n, for the project area must be determined by using the CDM A/R methodological tool *Calculation of the number of sample plots for measurements within*

A/R CDM project activities.[20] As soil is typically sampled from three or more pooled 5-10 cm diameter cores at a station and therefore from a small total area (< 0.05 m^2), there are potentially a large number of potential sampling sites in even the smallest project area (< 1 km^2). Consequently, the total number of sampling stations, according to the CDM tool, is largely insensitive to the total area of the project for a measured approach as shown in see Figure .

Figure 1: Estimate Number of Sampling Stations

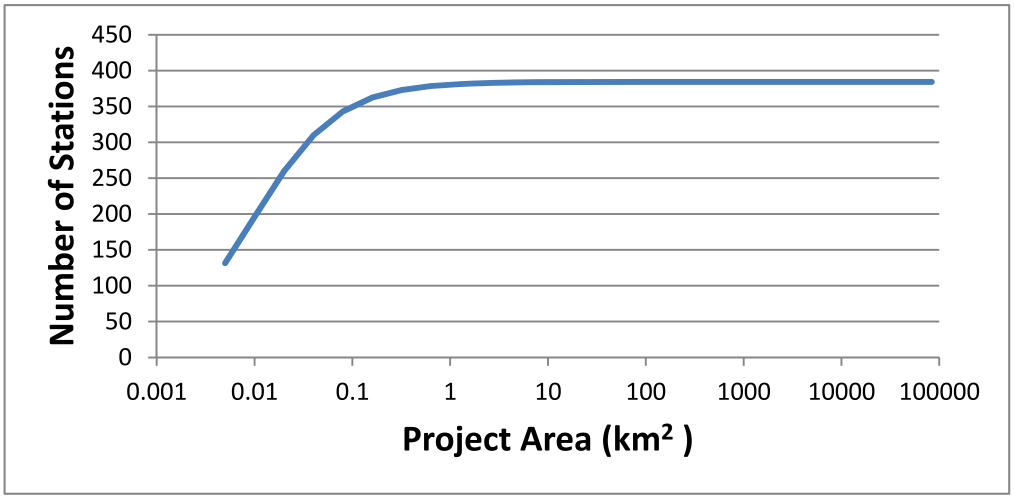

Figure 1 shows the estimated number of sampling stations needed to detect an increase in mean SOC of 0.3 percent for samples with a typically observed standard deviation of 0.3 percent (100 percent of mean) and target standard error of less than 10 percent.

8.1.2.2 Stratification

<u>Measured Approach</u>

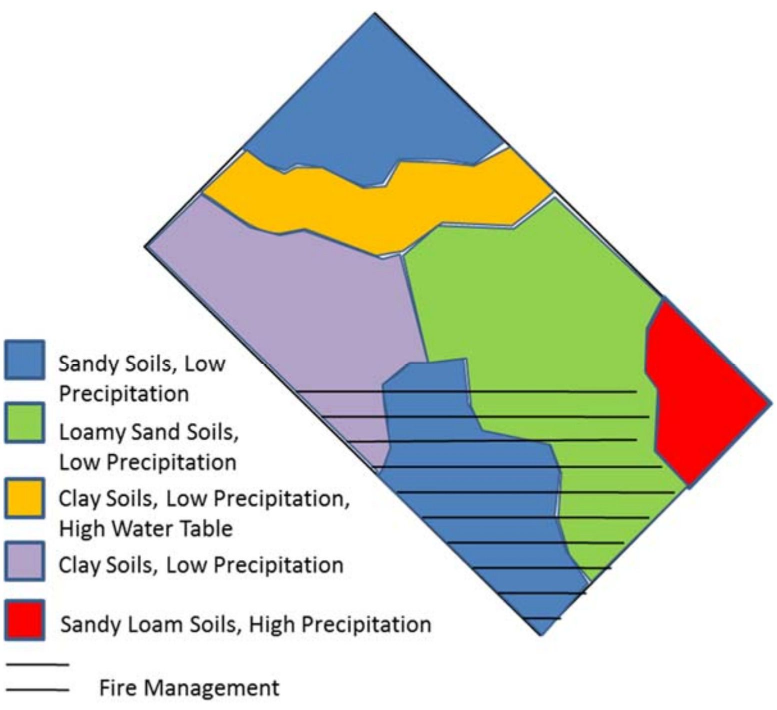
Obtaining precise estimates of soil organic carbon requires careful stratification[21, 22]. Stratification on the basis of vegetation and management practices must provide a good initial scope of stratification for soil, but additional factors, such as topography (top, middle and bottom of slopes), and texture (proportion of sand, silt and clay) may also be important for defining strata. A cluster, regression tree or other similar analysis of SOC from the permanent sampling stations, which is required to establish baseline SOC stocks, must be used to decide a final stratification. These types of analyses examine a set of different measurements from different locations to find groups of locations with similar values, and may be conducted in many ways depending on the extent of variability in soils, climate, and management in a project area[22]. For a detailed discussion and recommended approaches, see references [23, 24].

Rather than limit uncertainty in absolute measurement of SOC stocks, a modeled approach has the goal to reduce the 95 percent confidence interval of a regression line of predicted change in SOC relative to observed change in SOC. This imposes an additional emphasis for the distribution of sampling stations to include the largest possible variation in SOC, both in terms of the strata chosen and in sampling variation within strata.

Using cluster analysis, regression tree analysis or any other means, such as the latest version of the VCS module VMD0016 *Methods for stratification of the project area (X-STR), v1.0* [25], the project proponent must classify the area by past management practices and preliminary information about soils (such as from a soils map) and climatic conditions (such as from areas that are similar in aboveground productivity, or from rainfall maps). This step is equivalent to stratification in an afforestation / reforestation project[20] but focused on factors related to soil carbon sequestration[7], fire frequency, and animal distribution and management, and reduces the uncertainty in estimates of project removals of GHG. This will produce *s* strata within which baseline and project emissions are calculated, soil carbon changes and methane emissions will be monitored, and past (baseline) and proposed project management activities have been (are) implemented.

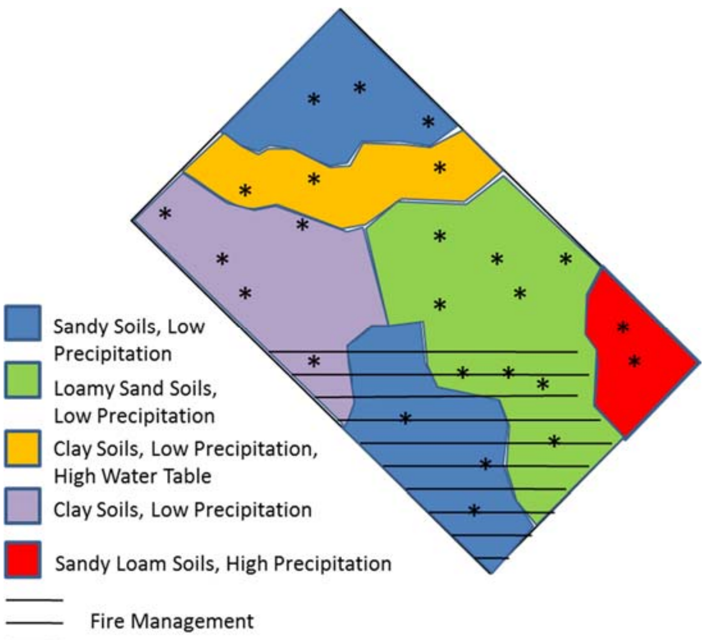
As an example, a project might be subdivided into five areas of different soil type and/or precipitation as seen in Figure . The sampling design would then feature eight strata, one for each combination of management activity, soil type, and precipitation or water availability.

Figure 2: Hypothetical Landscape among Eight Strata Subject to Different Management Practices



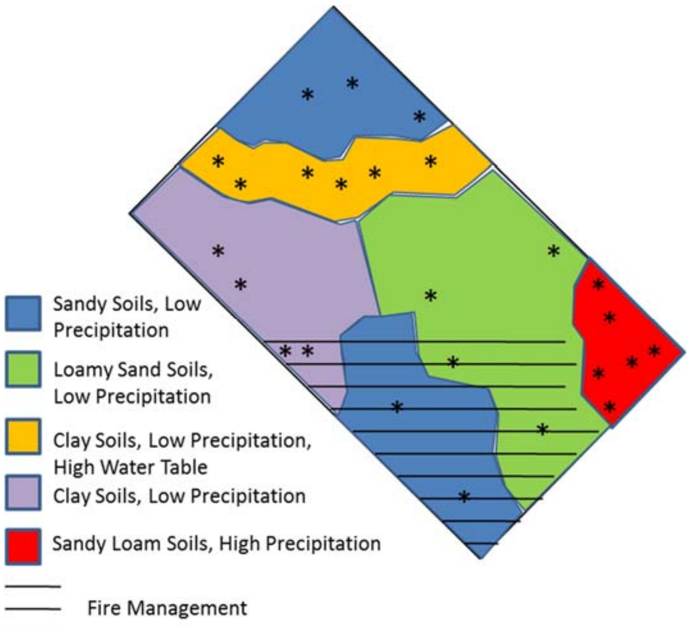
Once each stratum is defined and mapped and the total number of sampling stations determined, then a representative number of sample points, z_m, are chosen within each stratum. The number of points per stratum will depend on which stratified sampling method is used. Where SOC exhibits similar variability among strata (ie, coefficients of variation (standard deviation/mean) differ by less than 40% in areas with different soil, vegetation, or management practices), the number of stations per stratum must be proportional to the proportional area of each stratum in the project area. This is the most likely scenario under the expectation that strata for a project are selected to ensure a low variance (10 percent standard error) within each stratum. For example, in a project with three strata, A, B, and C that represent 50 percent, 40 percent and 10 percent respectively of the total project area and the project area requires 100 sampling stations, then 50, 40, and 10 stations must be placed randomly within each of strata A, B, and C as shown in **Error! Reference source not found.**3 below. This is the case of proportional allocation, which the number of stations is allocated to each stratum on the basis of its proportion of the total project area.

Figure 3: Proportional Allocation of Sampling Stations (Stars) Among the Eight Strata in the Hypothetical Project Area in Figure 2



Alternatively, the best possible stratification of the project area, resulting in the least uncertainty, may still feature certain strata that exhibit much higher variability (> 40% difference in coefficient of variation) in SOC than others. In this case, “optimum” or disproportionate allocation of stations may be most appropriate. Where a disproportionate application is applied, strata receive a number of sampling stations proportional to their coefficient of variation rather than their proportional area. In the example, hypothetical strata A, B, C might receive 20, 20, and 60 percent of stations, respectively if SOC in stratum C is three times more variable (three times higher coefficient of variation), regardless of their proportional areas. As an example, Figure 4 shows the disproportionate allocation of 25 sampling stations in the hypothetical project area shown below. In this case the high precipitation stratum and the clay soils with a high water table are three times more variable than other strata, and thus receive 6 stations, as opposed to two.

Figure 4: Optimal or Disproportional Allocation of Sampling Stations (Stars) Among the Eight Strata of the Hypothetical Project Area in Figure



The primary goal of the distribution of stations must be to reduce variability and increase representation of different SOC values in the project area.

Modeled Approach

For projects using a modeled approach, the objective is to demonstrate that the chosen soil carbon model can predict SOC stocks or changes in SOC stocks at each of a large number of sampling stations that differ in key factors, such as climate soil type, past management, and vegetation. Sampling stations must be selected to encompass as much of the variability in these factors as possible in order to test that the model is appropriate for use in the project area (see Section 8.1.3.3. The sample size must be determined using an online calculator[8] or a power analysis in any standard statistics program. As an example, to achieve the desired model accuracy of R^2 > 0.80 (see Section 8.1.3.3) and an uncertainty of less than 0.08, a total of 120 samples would be needed from across the full variation in SOC within the project area.

8.1.3 Calculation of Baseline Emissions

[8] One resource for online calculators is http://www.danielsoper.com/statcalc3

8.1.3.1 Baseline Emissions from Grazing Animals (BEM)

Baseline methane emissions from grazing animals must be estimated from data on total numbers for different livestock categories that reflect species, age, sex and their respective weights, in the project area. The methodology applies to Tier 2 approaches, as outlined in the *IPCC 2006 Guidelines for National Greenhouse Gas Inventories* Chapter 10, Emissions From Livestock and Dung Management[5] but with local input data. Calculations are based on estimating daily methane emissions as a function of the body weight (kg) of each major animal category [26] (Figure 5: Daily Methane Emissions Data), and then multiplied by the number of animals in each animal category and 365 days in a year. Emissions from all categories may then be summed to provide the total annual methane emissions for the project area. Domestic livestock grazing animals of category c must be classified as one of three animal types: ruminants (sheep, goats, cattle, buffalo, and camelids (ie, camels, alpacas, guanacos, llamas), equids (donkeys, horses) or pigs.

$$BEM = \sum_{c=1}^{K}\left(BN_C \times \ DMEF(W_c)\right) \times GWP_{CH_4} \times 365 \times 6.26x10^{-7} \quad (1)$$

Where:

BEM	= Baseline annual emissions from grazing animals (tCO_2e)
BN_c	= Baseline number of animals of category *c* (head)
$DMEF(W_c)$	= Daily emission factor as a function of animal weight for category *c* (L CH_4 / day)
$W_{C,}$	= Average body weight during the baseline period for animals of category *c* (kg)
GWP_{CH4}	= Global warming potential for methane (tCO_2e / tCH_4)
c	= category of grazing animals
K	= number of categories of grazing animals, eg species, gender, age combinations
365	= Conversion factor for days to years
6.26×10^{-7}	= Conversion factor for L CH_4 / day to t CH_4 / day

Further, $DMEF(W_c)$ is the daily emission factor (liters CH_4 / day) as a function of animal weight for animal category c. These values must be determined using the relevant allometric equations in **Error! Reference source not found.**.

Table 4: Allometric Equations, with Uncertainty, for Daily Methane Emissions for Three Animal Types: Ruminants, Equids, And Pigs

Animal Type	Equation	n	R^2	Uncertainty Percent
Ruminants	$0.66 \times W_C^{0.97}$	62	0.88	9.5%
Equids	$0.18 \times W_C^{0.97}$	23	0.76	28.2%
Pigs	$0.07 \times W_C^{0.99}$	12	0.93	18.6%

BN_c, is the harmonic mean number of animals of each category during the 10 years prior to the project start date, calculated as below. The harmonic mean conservatively weights lower values of methane emissions in a sample[27]. This must be calculated using equation (2). The harmonic mean BN_c for n censuses[27] of $N_{c,i}$ animals in each category c during census i is given by:

$$BN_c = \left(\frac{1}{n}\right) \times \left(\frac{1}{\sum_{i=1}^{n} \frac{1}{N_{c,i}}}\right) \quad (2)$$

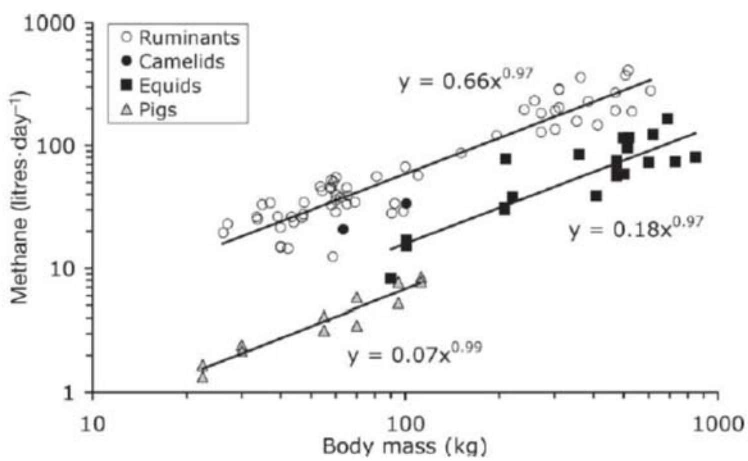
Where:

BN_c	= Baseline number of animals of category *c* (head)
n	= Number of counts
$N_{c,i}$	= Animals in category *c* during count *i* (head)

Calculations of uncertainty are given in Section 8.4.2.1.

Figure 5 shows the daily methane emissions data compiled from the Franz *et al.* (2010) review of 62 measurements for ruminants (sheep, goats, cattle and buffalo), 23 measurements for equids (donkeys and horses) and 12 measurements for pigs, showing how methane emissions scale with body weight W (kg). All animals were fed roughage forage similar in quality (40-50 percent neutral detergent fiber) to plants consumed in unfertilized grasslands that likely apply in this methodology. These relationships are summarized in **Error! Reference source not found.** above.

Figure 5: Daily Methane Emissions Data



Forage quality, and specifically the fiber content of forage, is known to affect methane emissions[28]. However, forage quality is not included because it introduces additional error into the calculation, since dry matter intake would also have to be estimated to yield methane emissions. Furthermore, the forage quality actually consumed, as opposed to that available, by free-living animals on grasslands can probably never be measured accurately across a large-scale project. So instead, it is expected that the uncertainties in the allometric equations in **Error!**

Reference source not found. are irreducible without impractical and prohibitively expensive direct methane measurements on individual animals[28] Depending on the relative abundance of equids in the composition of animals, this uncertainty in methane emissions may induce an uncertainty deduction in the calculation of removed methane emissions.

8.1.3.2 Baseline Emissions of Methane from Burning of Biomass (BEBB)

Biomass burning results in annual emissions of methane. These emissions may be conservatively excluded if project activities do not change or lead to decreased annual emissions, in which case BEBB = 0. If project activities decrease fire, proponents can choose to include biomass burning in baseline emission calculations and show the net decrease in such emissions under the project scenario. If project activities increase fire frequency, such as to remove shrubs and lead to a net increase in total carbon stocks from the increase in SOC associated with establishment of perennial grasses, project proponents must calculate the net change in emissions from biomass burning under the project scenario, BEBB, must be calculated with the following equation:

$$BEBB = \frac{\sum_{m}^{M}\left(FFREQ_{m,b} \times APB_{m,b} \times PA_{m,b}\right) \times BC_G \times EF_{BG} \times GWP_{CH_4}}{1{,}000{,}000} \quad (3)$$

Where,

BEBB	= Baseline annual emissions of methane from burning of biomass (tCO_2e)
$FFREQ_{m,}$	= Proportion of area of stratum *m* burned annually (percent)
$APB_{m,}$	= Mean total aboveground biomass at the end of the growing season in stratum *m* (kg biomass/ha)
$PA_{m,}$	= Baseline area in stratum *m* (ha)
BC_G	= Baseline combustion factor for savanna/grassland (kg biomass burned/kg biomass)
EF_{BG}	= Emission factor for the burning of grassland (g CH_4/kg biomass burned)
GWP_{CH4}	= Global warming potential of CH_4 (tCO_2e / tCH_4)
1,000,000	= Converts g CH_4 into Mg (tons)

8.1.3.3 Baseline Changes in SOC Density

The determination of a change in baseline equilibrium carbon density depends on the type of project approach used.

Measured Approach**.** Where the measured approach is applied, initial $SOC_{m,j,0}$ at each sampling station is the baseline. Initial $SOC_{m,j,0}$ may be calculated from multiple pooled soil cores from each station as:

$$SOC_{m,j,0} = DEPTH_{m,j,0} \times SOC\%_{m,j,0} \times BULK_{m,j,0} \quad (4)$$

Where:

$SOC_{m,j,0}$ = SOC density in station *j* in stratum *m* at time *t =0* (tC/ha)

$DEPTH_{m,j,0}$ = Depth of SOC sampling at the project start (cm)

$SOC\%_{m,j,0}$ = Percent SOC in dry soil from the entire soil profile to the chosen depth at station *j* in stratum *m* at time *t =0* (percent)

$BULK_{m,j,0}$ = Bulk density at station *j* in stratum *m* at time *t =0* (Mg dry soil / m^3) (Note Mg/m^3 are equivalent to g/cm^3, the unit most commonly reported by laboratory analyses)

Note that $SOC\%_{m,j,0}$ is a percent and allows the equation to correctly calculate SOC density (tons/ha).

$DEPTH_{m,j,0}$ must be selected by the project proponent to account for the vast majority (> 80 percent) of SOC in the soil column, reflect depth to hardpans or bedrock, or to match calculations from soil carbon models. $SOC\%_{m,j,0}$ and $BULK_{m,j,0}$ must be measured in a professional laboratory through either combustion methods[29] or multi-spectral diffraction with an infra-red spectrometer following project area-specific calibrations[30]. Bulk density accounts for whether soil is loosely or densely packed and must not include volume occupied by rock fragments or pebbles.

Modeled approach. Baseline management activities and environmental conditions driven by possible project activities, such as grazing intensity and fire frequency, as well as critical factors affecting carbon inputs and outputs to soil, such as soil texture, climate and plant characteristics that affect decomposition must be imported into a peer-reviewed, published soil carbon dynamics model that has been assessed for accuracy at least once with an independent set of data other than that used to construct the model. For example, SNAP[3] CENTURY[4, 16, 31], EPIC[32, 33], Hurley Pasture[34, 35] models are four models that incorporate grazing and/or fire, among others, as factors determining soil carbon.

One or more of these or other candidate models must be assessed for accuracy independently, (ie, with data other than that used to construct the model), and also tested to demonstrate it is appropriate for use in the project area by showing its ability to predict initial carbon stocks in different subareas (strata) within the project area (see below). This analysis assumes that past practices have been in place long enough for SOC to approach equilibrium. Thus the soil carbon model must be able to predict this equilibrium for strata in the project that have experienced similar management activities for 20 years or more. A regression line is fitted to a scatter-plot of model-predicted SOC (x-axis) vs. measured SOC from a large number permanent sampling stations[36] (see section 8.1.2.2). Variation in conditions and management activities across strata may be used as the source of different soil carbon model parameter inputs. The model must generate a coefficient of determination $R^2 > 0.80$ across all strata. The slope of the regression line must have a 95 percent confidence interval that overlaps 1 and the 95 percent confidence interval of the intercept must overlap zero. If these criteria cannot be met with any available models, then the project proponents must use the measured approach.

Bias must be determined by evaluating the percent bias of a simulation (carbon model) relative to observed data[37].

$$MBIAS = \frac{\sum_{i=1}^{n}({Y^{obs}}_i - {Y^{pred}}_i)}{\sum_{i=1}^{n} {Y^{obs}}_i} \quad (5)$$

Where:

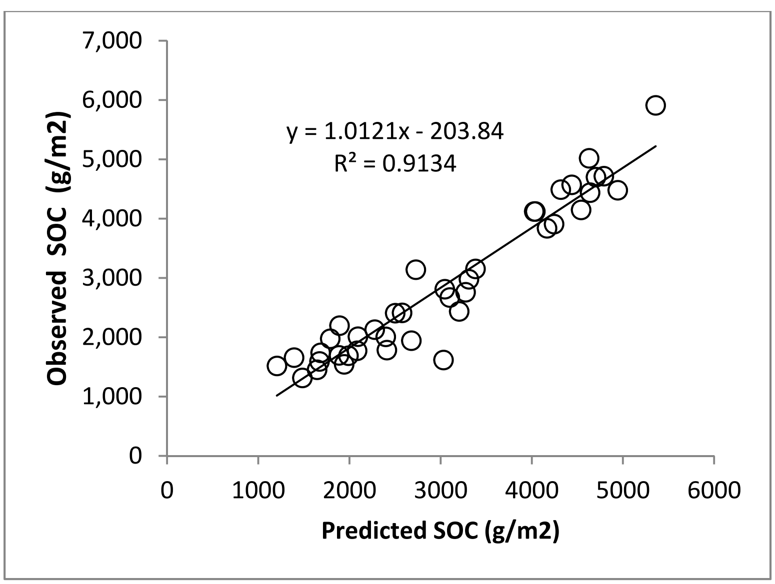
MBIAS	= Percent bias of carbon model predictions relative to observed data
n	= number of sampling stations tested
${Y^{obs}}_i$	= observed SOC density at station i
${Y^{pred}}_i$	= SOC density predicted at station i

Bias of the model chosen for this methodology must be between -20% and +20%.The criteria of $R^2 > 0.80$, slope = 1 and intercept = 0 should ensure that -20% ≤ MBIAS ≤ 20% [37]. In the case that significant bias is found and emission reductions are over-predicted— a subset of observed data may be used to adjust model parameters and fit the model to data, and then the model may be re-tested with the remaining data.

In addition the 95 percent confidence interval for predicted mean SOC, derived from Monte Carlo simulations, must overlap with that of SOC measured at sampling stations in the same stratum. If, for certain strata, the 95 percent confidence intervals do not overlap, then the soil carbon model must be calibrated for that stratum by adjusting one or more parameters until 95 percent confidence intervals do overlap.

Figure provides an example test of predicted SOC (g/m^2) of a soil carbon model with observed measured SOC, showing the regression line, coefficient of determination R^2 and the degree of variation around the regression line expected for an accurate, precise model for calculating baseline SOC and changes in SOC.

Figure 6: Example Test of Predicted SOC (G/M^2) of a Soil Carbon Model with Observed Measured SOC



The statistics of variation needed to calculate uncertainties for each parameter in the model are also necessary to determine an overall uncertainty in the model calculations of SOC. Total uncertainty of model predictions of baseline SOC, changes in SOC or eventual equilibrium SOC may be determined by an analysis called Monte Carlo simulation[3, 38]. In such a simulation, parameter values are randomly chosen from hypothetical normal distributions with mean equal to the parameter value and the measured standard error around that mean. Once all the different parameter values for the model are generated from the hypothetical distributions, a model prediction is made. This process is repeated 100 or more times to produce a mean model prediction with a 95 percent confidence interval. For baseline SOC, the Monte Carlo simulation would generate an expected value of SOC and a 95 percent confidence interval.

In some cases, alternative soil carbon models, and/or the same modeling framework with different sets of input parameters, may be appropriate for the same project area and activity[39]. If so, the project proponent must match predictions of different models to observed SOC and choose the model that best predicts current $SOC_{m,j,0}$ at each station in stratum m with the lowest Akaike Information Criterion (AIC) value, as per standard model selection procedures[40] Different models may use different numbers of parameters, so AIC is a statistic that measures the amount of variation in observation that is not predicted by a model, corrected for the number of parameters K used in the model to make the prediction:

$$AIC = n \times ln\left(\frac{\sum_{i=1}^{n} e_i^2}{n}\right) + 2K + 2K\left(\frac{K+1}{n-K-1}\right) \quad (6)$$

Where:

AIC	= Akaike Information Criterion value
n	= Number of observations tested, and
e_i	= Deviation of an observation from its model prediction
K	= Number of parameters used

Note that models, such as CENTURY[4, 16, 31], with large numbers of parameters (> 80) require a large number of observations n > K to even generate AIC, and such models would have to generate vastly greater fits (higher R^2, lower $\sum_{i=1}^{n} e_i^2$) to observations than much simpler models with fewer parameters, such as the Hurley Pasture model[2, 34, 35].

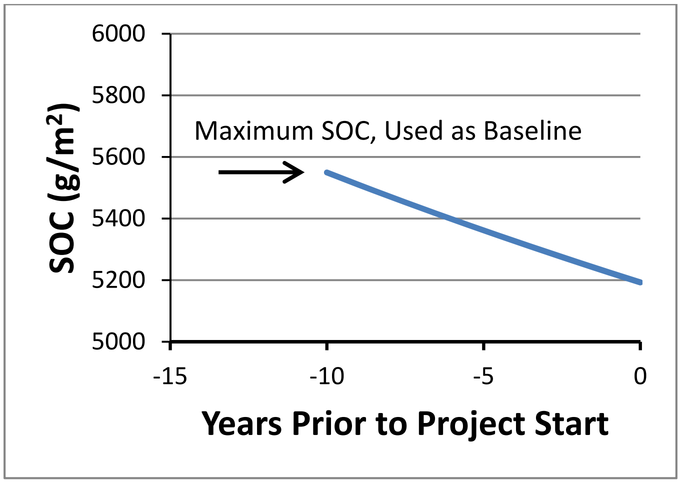
The chosen model must be re-calibrated as soon as changes in SOC may be measured (typically 5 or more years but up to a maximum of 10 years) since the project start date or most recent re-calibration (calibration period). In this case, the model should be used to detect the change in soil carbon during the previous calibration period rather than to predict carbon stocks. Necessary model parameters must be measured as discussed previously in this section and predictions of change in soil carbon stocks must be compared against measured changes at each of the permanent sampling sites using the regression approaches outlined previously in this section. Again, the model should predict observed change in soil carbon with $R^2 > 0.80$ and RMSR < 0.7. If the selected model fails to successfully predict soil carbon changes according to these criteria, then the project proponent may modify the model, or re-calibrate it. Re-calibration may occur by adjusting parameter inputs or coefficients in the model's functions in a reasonable way (justified by peer-reviewed scientific literature) to achieve successful prediction of changes in SOC during the calibration period.

8.1.3.4 Generating Baseline SOC with a Soil Carbon Model

Projects applying a modeled approach, must apply the maximum SOC in the previous 10 years as the baseline SOC stocks. For most projects, this will not have been measured, so the soil carbon model of choice must be used to "back cast," that is estimate SOC that would have occurred during the baseline period**.**

Figure **7**7 provides an example of back casting SOC change from current SOC, based on knowledge of past management activities and environmental conditions. The blue line is predicted SOC of previous years (x-axis). This example shows what baseline SOC would be 10 years prior (5549 g/m^2 at year 10) rather than current (5192 g/m^2 at year 1), thus increasing conservatism in the estimate of baseline SOC.

Figure 7: Example of Back-Casting SOC Change from Current SOC



Maximum baseline $MSOC_{m,j,0}$ for each station in each stratum must be estimated by back casting the chosen model (Figure 7: Example of Back-Casting SOC Change from Current SOC) with model input parameters associated with the soil type, plant species, climate and management activity of that stratum.

Overall, the soil carbon model may be used to estimate a modeled baseline SOC density, $MSOC_{m,j,0}$ = maximum SOC density (tons/ha) at sampling station *j* in stratum *m* during the baseline period.

$$MSOC_{m,j,0} = max(MSOC_{m,j,b}) \quad (7)$$

Where:

$MSOC_{m,j,0}$ = Modeled SOC in station *j* in stratum *m* at *time t =0* (tC / ha)

$MSOC_{m,j,b}$ = Modeled SOC in station *j* in stratum *m* for year *b* during the baseline period (tC / ha)

8.1.3.5 Baseline Emission Removals from Existing Woody Perennials (BRWP)

Under the applicability condition that baseline emissions derived from livelihood-driven human impacts on aboveground woody biomass must be negligible and project activities cannot significantly alter such livelihood-driven activities, it is likely that fire and grazing are the main drivers of change in aboveground woody vegetation. Where a reduction in fire frequency is a project activity, woody plant carbon stocks will increase as a consequence, and reversals of past and ongoing losses of woody plant biomass may be conservatively excluded (ie, BRWP = 0).

If past grazing pressure has been high enough to reduce fuel loads, past fire frequency may have been very low and woody plants, particularly shrubs, may have become abundant. If so, activities to sequester carbon may entail an increase in fire frequency that will reduce aboveground woody biomass but lead to an increase in soil carbon sequestration sufficient to increase total carbon stocks[1]. If fire is employed to change vegetation, aboveground woody biomass, must be accounted for in calculating project emissions and removals.

8.2 Project Emissions

Project emissions and removals depend on the principal set of project activities. Projects that reduce fire events need to account only for changes in methane emissions by grazing animals and changes in SOC. Projects that increase fire events to remove unpalatable woody plants—usually shrubs—in order to stimulate grass and root production can increase total carbon stocks. These projects must account for increased methane emission from biomass burning and emissions from decreased aboveground woody biomass carbon.

8.2.1 Project Methane Emissions from Grazing Animals (PEM_t)

If project activities will include reduction in livestock numbers, then accompanying removals from reduced methane emissions must be conservatively excluded from project removals. This avoids potential leakage from shifting of animals to adjacent grasslands or from market leakage whereby other producers increase livestock numbers to replace project livestock reductions and meet market demand. However, whether or not methane emissions from livestock are reduced, calculations must be based on project data from animal counts or censuses and emission factor data based on project area-applicable body weight of each category from the equations in **Error! Reference source not found.** and Equation (1) (Section 8.1.3.1).

$$PEM_t = \sum_{c=1}^{K} \left(PN_{C,t} \times DMEf\left(W_{C,t}\right)\right) \times GWP_{CH_4} \times 365 \times 6.26x10^{-7} \tag{8}$$

Where:

PEM_t = Project emissions of CH_4 from grazing animals at year t (tCO_2e)

$PN_{C,t}$	= Number of animals of each category *c* in year *t* (head)
$DMEf(W_{C,t})$	= Daily emission factor as a function of animal weight for category *c* (L CH_4 / day)
$W_{C,t}$	= Average body weight during year t for animals of category *c* (kg)
GWP_{CH4}	= Global warming potential for methane (tCO_2e / tCH_4)
365	= Conversion factor for days to years
6.26×10^{-7}	= Conversion factor for L CH_4 / day to tCH_4 / day

The parameters are similar to those used for calculating baseline methane emissions. The number of grazing animal must be measured, because new animal categories may result due to project activities (eg, there is a shift to using different breeds or species of livestock).

8.2.2 Project Emissions from Burning of Biomass ($PEBB_t$)

Where project activities reduce the frequency of fire, this emission may be conservatively excluded, in which case $PEBB_t = 0$. Where project activities increase fire frequency (eg, to remove shrubs) and lead to a net increase in total carbon stocks, the baseline emissions of methane due to burning of biomass, $PEBB_t$, t CO_2e, are calculated using the following equation:

$$PEBB_t = \frac{\sum_m^s \left(PFFREQ_{m,t} \times \left(\sum_{j=1}^{z_m} APB_{j,m,t}\right) \Big/ z_m \right) \times PA_{m,t} \times PC_G \times EF_{BG} \times GWP_{CH_4}}{1{,}000{,}000} \quad (9)$$

Where:

$PEBB_t$	= Project emissions of CH_4 due to biomass burning in stratum m in year t (tCO_2e)
$PFFREQ_{m,t}$	= Proportion of area of stratum *m* burned in year t (percent)
$APB_{j,m,t}$	= Aboveground plant biomass at sampling station *j* in stratum *m* in year *t* at the beginning of the dry/cold/ or burning season (kg biomass/ha)
z_m	= Number of sampling stations in stratum *m* at time *t*
$PA_{m,t}$	= Project area in stratum *m* at time *t* (ha)
PC_G	= Project combustion factor for savanna/grassland (kg biomass burned / kg biomass
EF_{BG}	= Emission factor for the burning of grassland (g CH_4 / kg biomass burned)
GWP_{CH4}	= Global warming potential of CH_4 (t CO_2e / t CH_4)
1,000,000	= factor for converting g CH_4 into tons

The project combustion factor (PC_G) may be estimated in two ways. The project proponent may apply the most applicable IPCC default value [9] or may measure the mean proportion of aboveground biomass after fire ($APB_{m,j,f}$) at the sampling stations in the project area that burned compared with the pre-fire aboveground biomass ($APB_{m,j,t}$) at each station *j* within each stratum *m*[42] :

[9] Table 2.6 in 41. IPCC, *Guidelines for National Greenhouse Gas Inventories* 2006. **4**(Chapter 2).

$$PC_G = 1 - \frac{\sum_{j=1}^{F}\left(\frac{APB_{j,m,f}}{APB_{j,m,t}}\right)}{F} \tag{10}$$

Where:

PC_G	= Project combustion factor for savanna/grassland (kg biomass burned/kg biomass
$APB_{j,m,f}$	= Aboveground plant biomass in stratum *m* in year *t* immediately following fire (kg biomass /ha)
$APB_{j,m,t}$	= Aboveground plant biomass at station *j* in stratum *m* in year *t* at the beginning of the dry/cold or burning season (kg biomass/ha)
F	= Number of sampling stations that burned

8.2.3 Project Changes in SOC Density

The determination of change from baseline equilibrium SOC density depends on the type of project approach used.

Measured Approach:

Where the measured approach is applied, the project sequestration of SOC (in t CO_2e/ha) is calculated using the following equation:

$$PRS_t = {}^{44}/_{12} \times \sum_{m=1}^{s} \frac{PA_m}{z_m} \times \sum_{j=1}^{z_m} \frac{SOC_{m,j,t} - SOC_{m,j,v}}{Y} \tag{11}$$

Where:

PRS_t	= Project removals due to changes in SOC stocks in year *t* (tCO_2e)
PA_m	= Project area of stratum *m* (ha)
s	= Number of strata in the project area
z_m	= Number of sampling stations in stratum *m*
$SOC_{m,j,,v}$	= Baseline SOC in station *j* in stratum *m* in year v, If this is the first monitoring period, v= 0, for subsequent monitoring periods, v represents the year of last verification (tC)
$SOC_{m,j,t}$	= Project SOC measured at station *j* in stratum *m* in year *t* (tC/ha)
Y	= Length of the monitoring period (years)
44/12	= Conversion factor from tC to tCO_2e

$$SOC_{m,j,t} = DEPTH_{m,j,t} \times SOC\%_{m,j,t} \times BULK_{m,j,t} \tag{12}$$

Where:

$SOC_{m,j,t}$	= Project SOC measured at station *j* in stratum *m* in year *t* (tC/ha)

$DEPTH_{m,j,t}$ = Soil core depth (cm)

$SOC\%_{m,j,t}$ = Percent soil carbon at time t (percent)

$BULK_{m,j,t}$ = Bulk density at station j in stratum m in year t (Mg dry soil/m^3; or equivalently, g dry soil/cm^3)

Note that this formula assumes that SOC in year Y and in year 0 (baseline or since last verification) will be measured at a large number (100-1000) of sampling stations j in a stratified project area, including z_m stations in each stratum m (see Section 0).

Modeled Approach:

The selected project area-validated soil carbon model (see Section 8.1.3.3) must be used to simulate a projected equilibrium SOC density, called the project modeled SOC, $PSOC^{eq}_{m,j}$ for sampling station in each stratum under expected project activities. Expected grazing intensities and/or fire frequencies under project activities will combine in the model with other parameters as needed for the chosen soil carbon model to generate $PSOC^{eq}_{m,j}$ for each sampling station The input parameters for the soil carbon model must be chosen to such that conservative estimates of carbon removals are generated. Uncertainties for each parameter in the model must be available to determine an overall uncertainty for $PSOC^{eq}_{m,j}$ with a Monte Carlo simulation[3, 43, 44], as discussed in detail in Section 8.1.3.3. The model must also calculate the number of years D to reach this equilibrium.

Carbon typically accrues in response to management changes with decreasing increments over time as equilibrium is approached[4, 33, 35]. Thus conservatively, the annual increment in SOC is determined by the difference in SOC between the conservative baseline maximum from 10 years prior to the project start ($MSOC_{m,j,0}$) and project modeled equilibrium ($PSOC^{eq}_{m,j,t}$) divided by the time necessary to achieve project equilibrium (D). The project equilibrium must be determined assuming that project activities will be implemented. Thus, multiplying the annual increment in SOC (tons/ha), by the conversion of C to CO_2 44/12 yields CO_2e at that station.

$$PRS_{m,t} = {}^{44}/_{12} \times \frac{PSOC^{eq}_{m} - MSOC_{m,0}}{D} \tag{13}$$

Where:

$PRS_{m,t}$ = Annual project removals due to changes in SOC stocks in stratum m in year t (tCO_2e /ha)

$PSOC^{eq}_{m,}$ = Project modeled equilibrium SOC at station j in stratum m (tC/ha) based on parameter values from z_m sampling stations in stratum m

$MSOC_{m,0}$ = Modeled SOC for stratum m at time $t=0$ (tC/ha) (see section 8.1.3.3)

D = Years required to achieve equilibrium

44/12 = Conversion factor from tC to tCO_2e

$$PRS_t = \sum_{m}^{s} (PA_{m,t} \times PRS_{m,t}) \quad (14)$$

Where:

PRS_t = Project removals due to changes in SOC stocks in year t (tCO_2e)
$PA_{m,t}$ = Project area of stratum m in year t (ha)
s = Number of strata in the project area
z_m = Number of sampling stations in stratum m
$PRS_{m,j,t}$ = Annual project removals due to changes in SOC stocks at station j in stratum m in year t (tCO_2e / ha)

8.2.4 Project Emissions and Removals from Existing Woody Plants ($PERWP_t$)

Where project activities involve changes in fire management, the project proponent must monitor changes in aboveground woody plant biomass (AWPB) to quantify sequestration of GHG in aboveground woody plant carbon from reductions in fire or to ensure that losses of woody biomass from increased fire do not outweigh potential gains from soil carbon sequestration. Where the project activities do not involve changes in fire management, the project proponent may exclude the aboveground and belowground woody biomass pool by assuming PERWP = 0.

$$PERWP_t = \frac{{}^{44}/_{12} \times C \times \sum_{m=1}^{s} \frac{PA_{m,Y}}{z_m} \times \sum_{j=1}^{z_m} AWPB_{m,j,0} - AWPB_{m,j,Y}}{1000 \times Y} \quad (15)$$

Where:

$PERWP_t$ = Project emissions from changes in aboveground woody biomass in year t (tCO_2e)
44/12 = Conversion factor from C to CO_2e
C = Proportion of wood composed of carbon[45, 46] (kg C/kg biomass)
$PA_{m,Y}$ = Project area of stratum m in year Y (ha)
z_m = Number of sampling stations in stratum m
s = Number of strata in the project area
$AWPB_{m,j,0}$ = Aboveground woody biomass at the project start date or beginning of the monitoring period at station j in stratum m; (kg biomass/ha)
$AWPB_{m,j,Y}$ = Aboveground woody biomass at station j in stratum m in year Y (kg biomass/ha)
Y = Length of the monitoring period (years)
1000 = Conversion factor from kg to t

8.3 Leakage

8.3.1 Estimation of Leakage

This methodology considers two forms of leakage: displacement leakage from the movement of livestock off the project area where they may reduce soil carbon, and market leakage, where reductions in livestock numbers as a project activity would create market incentives to replace the lost livestock.

$$LE_t = LD_t + LM_t \quad (16)$$

Where:

LE_t = total leakage emissions in year t (tCO_2e)

LD_t = leakage emissions from displaced livestock in year t (tCO_2e)

LM_t = emissions from market leakage in year t (tCO_2e)

8.3.1.1 Leakage Emissions From Displaced Livestock

Increased GHG emissions from the displacement of livestock outside the project area is limited by the applicability condition that the project must be structured to keep livestock within the project area, and the project proponent must be able to enforce the boundaries of the project area. The project proponent must prevent incursion of livestock from outside the project area or excursion of livestock from inside the project area through fencing, patrolling by game scouts, or other such enforcement of project area boundaries.

The project proponent is expected to control grazing animal numbers inside the project area and account for the number of animals involved and duration of any movement of livestock to outside the project area. Mechanisms must be in place to prevent incursion of livestock onto project lands and to monitor and prevent migration or transport of livestock out of project lands. Such mechanisms may include fencing of private lands, governance structures that penalize lack of cooperation and participation, education, and monitoring on communal grazing lands. Nevertheless, monitoring of project activities may reveal that livestock excursions outside the project area have occurred and any impacts of such excursions on GHG emissions or reductions outside the project area must be accounted for as leakage. Where the project area is not fenced, such as in pastoralist systems, the movement and excursion of livestock to more than two kilometers from the project area boundary is considered leakage.[10]

Leakage methane emissions are deemed as zero because movement of project livestock off the project area does not result in a net increase in the number of livestock emitting methane. However, movement of livestock could result in losses of carbon from higher levels of overgrazing off the project area. Leakage may be accounted in two possible ways: monitored approach or penalty approach.

---

[10] This distance allows for possible uncertainty of herders as to the position of herds in or out of the project area and is a typical allowable buffer between ethnic group communal grazing lands [48]

A monitored approach allows livestock to graze on either planned (identified) or unplanned (unidentified) land parcels outside the project area, such land parcels must be classified as grassland, forest, or cropland. In this approach, potential vegetation impacts and baseline SOC in these outside areas must be measured/monitored, following VMD0040 *Leakage from Displacement of Grazing Activities*.

The penalty approach is a more conservative option (leakage calculations will likely be larger) but no monitoring of soils and/or vegetation outside the project area is required and off-project area use of grasslands, croplands, and forests is not differentiated. In this case, displacement leakage (LD_t) must be calculated as a proportion of net removals from increased soil carbon in year t (PRS_t), based on the proportion of total project livestock-days in project year t, 365 x $PN_{c,t}$, that occurred outside the project area.

$$LD_t = \frac{\sum_{x=1}^{d}\sum_{c=1}^{k} DN_{c,x}}{365 \times \sum_{c=1}^{k} PN_{c,t}} \times PRS_t \tag{17}$$

Where:

LD_t	= Leakage emissions from displaced livestock (tCO_2e)
$DN_{C,x}$	= Number of livestock of each category c that were off the project area on day x (head)
d	= Total number of days livestock were off the project area
k	= Total number of livestock categories
$PN_{C,t}$	= Number of animals of each category c in year t (head)
PRS_t	= Project removals due to changes in SOC stocks in year t (tCO_2e)

Alternatively, where using the monitored approach to calculating leakage, the methods for accounting for losses of SOC in VCS module VMD0040 (in Sections 5.2.4 through 5.2.6) must be followed for unidentified grasslands, croplands, and forests. Because this approach explicitly estimates actual losses of SOC from livestock grazing, it is more accurate in its calculation of leakage, and requires the measurement of many additional parameters, as defined in the module. The project proponent, for example, whose livestock were displaced only onto additional grasslands, would be required to measure a number of parameters including, the area of parcels affected, aboveground net primary production, and the number of livestock using the area prior to livestock displacement and following displacement. The monitored approach to calculating displacement leakage does not need to account for CH_4 or N_2O emissions. Methane emissions from project livestock will not change even if livestock are displaced off the project area, and the applicability conditions limit any net increase in dung deposition. Other impacts, such as deforestation or degradation associated with livestock use of forests, or removal of crop residues by livestock must be included in leakage calculations using the monitored approach, if they cannot be shown to be negligible (ie, greater than 0.05 x PER_t, equation 18)

8.3.1.2 Market Leakage Emissions

These result from an increase in activity by other producers of a commodity outside the project area to compensate for the reduced supply of a commodity from within the project area, such as increased timber harvesting elsewhere in a country to compensate for reduced harvesting in a project area). Market leakage is generally considered to be minimal in ALM projects[47] because the projects still allow the same livelihood choices and production of grassland commodities (eg, livestock). The applicability condition that limits project size, and thus potential impact of the project on national and international markets, reduces the chance that project activities will result in declining supply of livestock. Nevertheless, market leakage for any reductions in livestock must be made by using the VCS module VMD0033 "Estimation of emissions from market leakage"[11] to estimate LM_t emissions from market leakage.

Fire alterations are not expected to dramatically alter livelihood choices, (eg, would not prevent use of land for livestock, wildlife conservation, tourism). Projects that manage fire or otherwise do not reduce livestock need not account for market leakage.

Total leakage is negligible where:

$$LE_t < 0.05 \times PNR_t \tag{18}$$

Where:

LE_t	= Total leakage emissions (tCO_2e)
PNR_t	= Project emissions plus removals in year t (tCO_2e)

8.4 Net GHG Emission Reduction and Removals

The estimation of net project emission reductions, PER_t, and net change in carbon stocks, $NCCS_t$, each year of the monitoring period is calculated using the following equation:

$$PER_t = PEM_t + PEBB_t - BEM - BEBB \tag{19}$$

Where:

PER_t	= Net project emission reductions in year t (tCO_2e)
PEM_t	= Project methane emissions from livestock in year t (tCO_2e)
$PEBB_t$	= Project emissions from biomass burning in year t (tCO_2e)
BEM	= Baseline methane emissions from livestock (tCO_2e)
$BEBB$	= Baseline emissions from biomass burning (tCO_2e)

Note that if project methane emissions decrease relative to the baseline from removal of livestock from the project area (note, not from forage improvement), ie $PEM_t - BEM < 0$, this GHG removal must be conservatively excluded to avoid market leakage, and proponents must set $PEM_t - BEM = 0$.

[11] http://www.v-c-s.org/sites/v-c-s.org/files/VMD0033%20Estimation%20of%20Emission%20from%20Market%20Leakage%2C%20v1.0.pdf

$$NCCS_t = PRS_t \pm PERWP_t \qquad (20)$$

Where:

$NCCS_t$	= Net change in carbon stocks in year t (tCO_2e)
PRS_t	= Project removals due to sequestration of soil carbon in year t (tCO_2e)
$PERWP_t$	= Project removals due to loss or gain of carbon stocks in woody biomass in year t (tCO_2e)

The net GHG benefit is calculated using the following equation:

$$R_t = PER_t + NCCS_t - LE_t \qquad (21)$$

Where:

R_t	= Net GHG emission reductions and removals in year t (tCO_2e)
PER_t	= Net project emission reductions in year t (tCO_2e)
$NCCS_t$	= Net change in carbon stocks in year t (tCO_2e)
LE_t	= Total leakage changes in soil carbon in year t (tCO_2e)

8.4.1 Ex-Ante Calculations of Net Emissions and Removals

The project must perform an ex-ante (before project) calculation of expected or estimated net emissions and removals. The key to making such a calculation is to define project quantitative management objectives for fire frequency and/or grazing management compared to baseline activities. The project proponent must do the following:

1) Show a table of baseline and proposed project scenario management activities.
2) Show a table of expected parameters and emissions and removals, and their uncertainties, associated with those management objectives; use data from the peer-reviewed literature, measure activities in the project area, or calculate with a model the resulting changes in emissions and removals associated with the management.
3) Calculate expected project scenario emissions and removals, and their uncertainties, based on these management targets.
4) Show a table of baseline emissions, project emissions and removals, leakage (if any), and total net greenhouse gas emissions and removals for each year of the project crediting period.

8.4.2 Estimation of Uncertainty

The *VCS Standard*[49] requires that uncertainty be calculated on the basis of the full width of the 95 percent CI expressed as a percentage of the estimate of each emission or removal. IPCC Guidelines[43] recommend using a Tier 2 approach to determine uncertainty where emission reductions are determined by a combination of measurements, published emission factors, and process models, such as a soil carbon model. A Tier 2 approach involves conducting Monte Carlo simulations[3, 38], which must calculate R_t from equation (21) (see section 8.4) more than 100 times, with each calculation drawing randomly from hypothetical normal distributions of expected values of each parameter in the calculation, as defined by the mean and standard errors of each parameter. This simulation gives a mean and standard deviation of net emissions and removals R_t that are used to calculate uncertainty (equation (22)). Such Monte Carlo simulations may be done in online computing environments, such as the R Project for Statistical Computing[48], or even with macros developed for spreadsheets[44].

$$UNR_t = \frac{3.84 \times 100 \times SD(MCR_{t,n})}{MCR_t \times (n-1)^{1/2}} \quad (22)$$

Where:

UNR_t = total uncertainty in net emission reductions and removals, not including leakage (%)

n = number of Monte Carlo simulation runs performed (must be > 100)

MCR_t = mean net emissions reductions and removals at time *t*, from *n* Monte Carlo calculations of R_t, (tCO_2e)

$SD(MCR_{t,n})$ = standard deviation of R_t from *n* Monte Carlo simulations

Alternatively, total uncertainty may be calculated by weighting uncertainties according to the magnitude of emission or removal. In this case, uncertainty in net reductions and removals UNR_t is driven by uncertainty in baseline emissions, project emissions and project net changes in carbon stocks.

$$UNR_t = \frac{((\mathrm{UPE}_t \text{ x } (\mathrm{PEM}_t + \mathrm{PEBB}_t))^2 + (\mathrm{UNCCS}_t \text{ x } \mathrm{NCCS}_t)^2 + (\mathrm{UBE} \text{ x } (\mathrm{BEM} + BEBB))^2)^{1/2}}{PEM_t + PEBB_t + NCCS_t + BEM + BEBB} \quad (23)$$

Where:

UNR_t = uncertainty in net emission reductions and removals, not including leakage, at time *t* (%)

UPE_t = uncertainty in project emissions at time *t* (%)

$UNCCS_t$ = uncertainty in net change in carbon stocks at time *t* (%)

UBE = uncertainty in baseline emissions (%)

BEM = baseline animal methane emissions (tCO_2e)

PEM_t = project animal methane emissions at time *t* (tCO_2e)

BEBB = baseline emissions from biomass burning (tCO_2e)

$PEBB_t$ = project emissions from biomass burning (tCO_2e)

$NCCS_t$ = net project changes in carbon stocks (tCO_2e)

Each of the three component uncertainties are derived in detail below

8.4.2.1 Uncertainty in the Baseline

For the calculation of baseline emissions and reductions, BER, uncertainty arises in the calculation of methane emissions only, because all other net emissions are conservatively assumed to be zero, unless increasing fire frequency is a proposed management activity.

In this case:

$$UBE = UBEM \tag{24}$$

Where:

UBE = Uncertainty in baseline emissions (%)

UBEM = Uncertainty in baseline methane emissions from grazing animals (go to section 8.4.2.1.1) (%)

In the case of proposed activities to increase fire frequency:

$$UBE = \frac{((BEM \times UBEM)^2 + \sum_{m=1}^{s}(UBEBB_m \times BEBB_m)^2)^{1/2}}{BEM + \sum_{m=1}^{s} BEBB_m} \tag{25}$$

Where:

$UBEBB_m$ = Uncertainty in baseline methane emissions from burning of biomass (%)

BEM = baseline methane emissions from animals (tCO_2e)

BEBB = baseline emissions from burning of biomass (tCO_2e)

8.4.2.1.1 Uncertainty in baseline methane emissions from grazing animals (UBEM)

$$UBEM = \frac{(\sum_{c=1}^{k}(BEM_c \times UBEM_c)^2)^{\frac{1}{2}}}{\sum_{c=1}^{k} BEM_c} \tag{26}$$

Where:

UBEM = Uncertainty in baseline methane emissions from grazing animals (%)

$UBEM_c$ = Uncertainty in baseline methane emissions from animals in category *c* (%)

BEM_c = Baseline emissions from animals in category *c* (tCO_2e)

$UBEM_c$ is the uncertainty in methane emissions from animals in category c, as dictated by whether the animals are ruminants, equids, or pigs (see Section 8.1.3.1),. $UBEM_c$ is calculated from the uncertainty, for each animal category, in the regression equations predicting per animal daily methane emission (DME_c) based on the mean body weight ($UDME_c$, **Error! Reference source not found.**) and the uncertainty in the harmonic mean of animal counts (UBN_c) during the baseline period.

To obtain UBN_c , first find $SEBN_c$, the standard error[50] of the harmonic mean BN_c of the series' $N_{c,i}$ of animals in category *c* in count *i* of *n* counts or censuses.

$$SEBN_c = (BNc)^2 \times \frac{SD\left(\frac{1}{N_{c,i}}\right)}{(n-1)^{1/2}} \quad (27)$$

Where:

$SEBN_c$	= Standard error of the harmonic mean of animal counts in category *c*
$SD(1/N_{c,i})$	= Standard deviation of the inverses of the count *I* of animals in category *c*
$N_{c,i}$	= Animals in category *c* in census *i* (head)
BN_c	= Harmonic mean number of animals in category *c* (head) during the baseline period (head)
n	= Number of censuses

The 95 percent confidence interval-based uncertainty in the estimated number of animals in category *c* is:

$$UBN_c = 3.84 \times 100 \times \frac{SEBN_c}{BN_c} \quad (28)$$

Where:

UBN_c	= Uncertainty in the harmonic mean of animal counts (%)
$SEBN_c$	= Standard error of the harmonic mean of animal counts
BN_c	= Baseline number of animals of category *c* (head)
3.84	= Multiplier converts expression into a 95% confidence interval
100	= Multiplier converts expression into percent

$$UBEM_c = \left(UBN_c{}^2 + UDME_c{}^2\right)^{1/2} \quad (29)$$

Where:

$UBEM_c$	= Uncertainty in baseline methane emissions from animals in category *c* (%)
UBN_c	= Uncertainty in the baseline harmonic mean of animals of category *c* (%)
$UDME_c$	= Uncertainty in the regression for predicting daily methane emissions for animals of category *c* (%)

8.4.2.1.2 Baseline methane emissions from burning of biomass (BEBB)

In the case of project activities that increase fire frequency, uncertainty in BEBB (UBEBB) is driven by uncertainty in fire frequency ($UFFREQ_m$) in stratum *m* (or mean proportion of area burned), and uncertainty in mean within-stratum aboveground plant biomass at the end of the growing season, $UAPB_m$. $UFFREQ_m$ arises from either the 95 percent confidence interval in annual variation in proportion of area burned over a period of 10 or more years prior to the start date or from uncertainty in the interpretation of satellite images in burned area mapping in stratum *m* resulting from mis-identification or classification errors of burned versus unburned areas[19].

$$UFFREQ_m = 3.84 \times \frac{SD(FFREQ_{m,BY})}{FFREQ_m \times (BY-1)^{1/2}} \times 100 \quad (30)$$

Where:

$UFFREQ_m$	= uncertainty (%) in fire frequency within stratum *m*
$SD(FFREQ_{m,t})$	= standard deviation in fire frequency in stratum *m* over *BY* years in the baseline period.
BY	= number of years in baseline period for which burned area is measured
$FFREQ_m$	= mean proportion of area burned during the baseline period
100	= converts the expression into percent
3.84	= converts the numerator into a 95% confidence interval

$UAPB_m$ arises from the 95 percent confidence interval among permanent sampling stations in clipped, dried, and weighed biomass.

$$UAPB_m = 3.84 \times 100 \times \frac{SD(APB_{z_m})}{APB_m \times (z_m - 1)^{1/2}} \qquad (31)$$

Where:

$UAPB_m$	= uncertainty in aboveground plant biomass within stratum *m*
$SD(APB_{zm})$	= standard deviation in aboveground plant biomass among z_m permanent sampling stations in stratum *m*
z_m	= number of sampling stations in stratum *m*
APB_m	= mean aboveground plant biomass in stratum *m* (kg/m^2)

Therefore these two sources of uncertainty combine as

$$UBEBB = \frac{\left(\sum_m^s \left(BA_m \times \left(UFFREQ_m{}^2 + UAPB_m^2\right)^{1/2}\right)^2\right)^{1/2}}{PA} \qquad (32)$$

Where:

UBEBB	= Uncertainty in baseline methane emissions from burning of biomass
$UFFREQ_m$	= Uncertainty in the fire frequency in stratum *m*
$UAPB_m$	= Uncertainty in mean within-stratum aboveground plant biomass at the end of the growing season in stratum *m*
BA_m	= Baseline area of stratum *m* (ha)
PA	= size of the project area (ha)
s	= number of strata

8.4.2.2 Uncertainty under the project scenario

Uncertainty under the project scenario using a weighted uncertainty approach is determined by uncertainty in project emissions or in carbon stocks, weighted by the magnitude of each, for each year of the monitoring period.

$$UPE_t = \frac{\left((PEM \times UPEM)^2 + \sum_{m=1}^{s}\left(PEBB_{m,t} \times UPEBB_{m,t}\right)^2\right)^{\frac{1}{2}}}{PEM + \sum_{m=1}^{s} PEBB_{m,t}}$$

(33)

Where:

UPE_t = Uncertainty in project emissions (%)

UPEM_t = Uncertainty in project methane emissions from grazing animals (%)

UPEBB_m,t = Uncertainty in project methane emissions from burning of biomass (%)

PEM = project methane emissions by animals during the monitoring period (tCO_2e)

PEBB_m,t = project emissions from biomass burning in stratum *m* at time *t* (tCO_2e)

$$UNCCS_t = \frac{\left(\sum_{m=1}^{s}\left(PRS_{m,t} \times UPRS_{m,t}\right)^2 + \sum_{m=1}^{s}\left(PERWP_{m,t} \times UPERWP_{m,t}\right)^2\right)^{1/2}}{\sum_{m=1}^{s} PRS_{m,t} + \sum_{m=1}^{s} PERWP_{m,t}}$$

(34)

UNCCS_t = Uncertainty in net changes in carbon stocks (%)

UPRS_m,t = Uncertainty in project reductions from soil sequestration (%)

UPERWP_m,t = Uncertainty in project emissions or removals from woody plants (%)

PRS_m,t = Removals from changes in soil carbon stocks in stratum *m* at time *t* (tCO_2e)

PERWP_m,t = Removals from changes in woody plant carbon stocks in stratum *m* at time *t* (tCO_2e)

8.4.2.2.1 Uncertainty in Project Methane Emissions

$$UPEM = \frac{\left(\sum_{c=1}^{k}(PEM_c \times UPEM_c)^2\right)^{1/2}}{\sum_{c=1}^{k} PEM_c} \quad (35)$$

Where:

UPEM = Uncertainty in project methane emissions from grazing animals during the monitoring period (%)

UPEM_c, = Uncertainty in project methane emissions from animals in category *c* (%)

PEM_c = project methane emissions from animals in category *c* (tCO_2e)

$UPEM_{c,}$ is the uncertainty in methane emissions calculated from the uncertainty, for each animal category, in the regression equations for per animal daily methane production (**Error! Reference source not found.**) and the uncertainty in the arithmetic mean of animal censuses for category *c*, PN_c, during the monitoring period.

$$UPEM_{c,} = \left(UPN_c{}^2 + UDME_c{}^2\right)^{1/2} \quad (36)$$

Where:

UPN_c = Uncertainty in the project mean of animals of category *c*

$$UPN_c = 3.84 \times 100 \times \frac{SD(PN_{c,Y})}{PN_c \times (Y\text{-}1)^{1/2}} \quad (37)$$

Where:

$SD(PN_{c,Y})$ = Standard deviation of animal counts in category *c* across Y years of the monitoring period

PN_c = Arithmetic mean of animal numbers in category *c* (head)

Y = Years in the monitoring period

3.84 = Multiplier that converts the numerator into a 95% confidence interval

100 = Multiplier that converts the expression into percent

$UPME_c$ = Uncertainty in the regression, taken from the literature (Table 4) for predicting daily methane emissions for animals of category *c*

8.4.2.2.2 Uncertainty in Project Emissions From Burning Of Biomass

In the case of project activities that increase fire frequency, uncertainty in PEBB, or UPEBB, is driven by uncertainty in fire frequency ($UFFREQ_m$) in stratum *m* (or mean proportion of area burned), and uncertainty in mean within-stratum aboveground plant biomass at the end of the growing season, $UAPB_m$. $UFFREQ_m$ arises from either the 95 percent confidence interval in annual variation in proportion of area burned over the period since last validation or from uncertainty in the interpretation of satellite images in burned area mapping in stratum m resulting from misidentification or classification errors of burned versus unburned areas[19]. $UAPB_m$ arises from the 95 percent confidence interval among permanent sampling stations in clipped, dried, and weighed biomass. Consequently:

$$UPEBB_{m,t} = \left(UPFFREQ_{m,t}{}^2 + UAPB_{m,t}{}^2\right)^{1/2} \quad (38)$$

Where:

$UPEBB$ = Uncertainty in project methane emissions from burning of biomass (%)

$$UPFFREQ_m = 3.84 \times 100 \times \frac{SD(PFFREQ_{m,Y})}{PFFREQ_m \times (Y\text{-}1)^{1/2}} \quad (39)$$

Where:

$UPFFREQ_m$ = Uncertainty in the project fire frequency in stratum *m* (%)

$PFFREQ_m$ = Mean proportion of area of stratum *m* burned during the Y years of the monitoring period

$SD(PFFREQ_{m,Y})$ = Standard deviation in project area of stratum *m* burned during the *Y* years of the monitoring period

$$UAPB_m = 3.84 \times 100 \times \frac{SD(APB_{m,Y})}{APB_m \times (Y-1)^{1/2}} \quad (40)$$

Where:

$UAPB_m$	= Uncertainty in mean within-stratum aboveground plant biomass at the end of the growing season in stratum *m* (%)
APB_m	= mean aboveground plant biomass at the end of the growing season (kg/m^2)
Y	= number of years in the monitoring period
3.84	= multiplier that converts the numerator into a 95% confidence interval
100	= multiplier that converts the expression into percent

8.4.2.2.3 Uncertainty In Project Soil Removals

Under a measured approach, uncertainty in soil sequestration, $UPRS_{m,t}$ in stratum *m* in year *t* is obtained from the 95 percent confidence interval, as required by the VCS rules[47, 49] of measured change in SOC across z_m sampling stations in stratum *m*.

$$UPRS_{m,t} = \frac{SD\Delta SOC_m \times 100 \times 3.84}{\Delta SOC_m \times (z_m - 1)^{1/2}} \quad (41)$$

Where:

$UPRS_{m,t}$	= uncertainty in project soil removals in stratum *m* at time *t* (%)

$$\Delta SOC_m = \sum_{j=1}^{z_m} \frac{SOC_{m,j,t} - SOC_{m,j,v}}{Y} \quad (42)$$

Where:

ΔSOC_m	= Mean of the difference in SOC between the beginning of the project or monitoring period, time *v*, and the year of monitoring *t*, across z_m sampling stations in stratum *m* (tC/ha)

$$SD\Delta SOC_m = \frac{SD(\Delta SOC_{m,z_m})}{(z_m - 1)^{1/2}} \quad (43)$$

Where:

$SD\Delta SOC_m$	= Standard deviation of ΔSOC in stratum *m* during the monitoring period across z_m sampling stations in stratum *m*
Y	= Number of years in the monitoring period
z_m	= Number of sampling stations in stratum *m*
3.84	= Multiplier that converts the numerator into a 95% confidence interval
100	= Multiplier that converts the expression into percent

Under a modeled approach, $UPRS_{m,t}$ is obtained from the calculated 95 percent confidence interval, as required by the VCS[47, 49] from a Monte Carlo simulation of modeled changes in soil carbon (see Sections 8.4.2 and 8.1.3.3) averaged across *n model runs* in stratum *m*.

$$UPRS_{m,t} = 3.84 \times 100 \times \frac{SDMOD\Delta SOC}{MOD\Delta SOC \times (n-1)^{1/2}} \quad (44)$$

Where:

$UPRS_{m,t}$	= Uncertainty in project removals through increased soil carbon in stratum *m* at time *t* (%)
$SDMOD\Delta SOC_m$	= Standard deviation of more than 100 modeled SOC estimates for stratum *m* from Monte Carlo simulation.
$MOD\Delta SOC_m$	= Mean modeled project equilibrium SOC for stratum *m* from more than 100 simulations of project equilibrium SOC, (tC/ha)
n	= Number of times simulation is run (must be greater than 100)
3.84	= Multiplier to convert standard error into a 95% confidence interval
100	= Multiplier to convert to percent

8.4.2.2.4 Uncertainty In Project Emissions And Removals From Woody Plant Biomass

Uncertainty in emissions from loss or gain of aboveground woody plants $UPERWP_{m,t}$ arises from three sources: Consequently, uncertainty in removals or emissions from changes in aboveground woody plant biomass, $UPERWP_{m,t}$, must be calculated as follows:

$$UPERWP_{m,t} = \left(UAWPB_{m,t-1}{}^2 + UAWPB_{m,t}{}^2 + UWD_m{}^2\right)^{1/2} \quad (45)$$

Where:

$UPERWP_{m,t}$	= Uncertainty in project emissions and removals from woody plants in stratum *m* in year *t*
$UAWPB_{m,t-1}$	= Uncertainty in project emissions and removals from woody plant biomass in stratum *m* at the project start date or the previous (year = t-1)
$UAWPB_{m,t}$	= Uncertainty in project emissions and removals from woody plant biomass in stratum *m* in year *t-1*
UWD_m	= Uncertainty in wood density in stratum *m*

(1) Among plot variation in initial (baseline) aboveground woody plant biomass in stratum m, $UAWPB_{m,0}$

$$UAWPB_{m.0} = \frac{SD(AWPB_{m.z_m}) \times 100 \times 3.84}{AWPB_m \times (z_m - 1)^{1/2}} \quad (46)$$

Where:

SD($AWPB_{m,zm}$) = Standard deviation of aboveground woody plant biomass across z_m sampling stations in stratum *m*.

$AWPB_m$ = Mean woody plant biomass across z_m sampling stations in stratum *m* (kg/m^2)

3.84 = Multiplier to convert expression to 95% confidence interval

100 = Multiplier to convert expression to percent

(2) Among plot variation in initial (baseline) aboveground woody plant biomass in year t of verification in stratum m: $UAWPB_{m,t}$,

$$UAWPB_{m,t} = \frac{SD(AWPB_{m,t,.z_m}) \times 100 \times 3.84}{AWPB_{m,t} \times (z_m - 1)^{1/2}} \quad (47)$$

SD($AWPB_{m,t,zm}$) = standard deviation of aboveground woody plant biomass across z_m sampling stations in stratum *m* at time *t* since the project start or last verification.

$AWPB_{m,t}$ = mean woody plant biomass across z_m sampling stations in stratum *m* at time *t* since the project start or last verification (kg/m^2).

3.84 = multiplier to convert numerator to 95% confidence interval

100 =multiplier to convert expression to percent

and

(3) Among plot variation in wood density: *UWD_m*

$$UWD_m = \frac{SD(WD_{m.z_m}) \times 100 \times 3.84}{WD_m \times (z_m - 1)^{1/2}} \quad (48)$$

Where:

SD($WD_{m,zm}$) = standard deviation of wood density across z_m sampling stations in stratum *m* at time *t* since the project start or last verification.

$WD_{m,}$ = mean wood density across z_m sampling stations in stratum *m* (g/cm^3)

3.84 = multiplier to convert expression to 95% confidence interval

100 = multiplier to convert expression to percent

8.4.2.2.5 Uncertainty in Leakage Emissions and Removals

If leakage is not negligible, uncertainty in leakage must be calculated as

$$ULE_t = \left(ULD_t^{\,2} + ULM_t^{\,2}\right)^{1/2} \quad (49)$$

Where

ULE_t = uncertainty in total leakage (%)

ULD_t = uncertainty in displacement leakage (%)

ULM_t = uncertainty in market leakage (%)

$$ULD_t = UPRS_t \quad (50)$$

Where:

$UPRS_t$ = Uncertainty in project removals due to changes in soil carbon stocks in year *t* (%).

This assumes that displacement leakage affects only soil carbon removals, and thus is subject to uncertainty associated with predicting impacts project activities on soil carbon removals

Uncertainty in market leakage, ULM_t, will be determined by using VCS module VMD0033 "Estimating emissions from market leakage."

8.4.2.3 Total Project Uncertainty

The total project uncertainty UT_t is calculated at the time of reporting through propagating the uncertainty in the baseline emissions and that in the project emissions and removals to year t:

Under a Monte Carlo calculation

$$UT_t = (UNR_t^2 + ULE_t^2)^{1/2} \quad (51)$$

Where

UT_t = total project uncertainty (%)

UNR_t = uncertainty in net emissions and removals as calculated with Monte Carlo simulation (%)

ULE_t = uncertainty in leakage emissions and removals (%)

$$UT_t = \frac{((NR_t \times UNR_t)^2 + (LE_t \times ULE_t)^2)^{1/2}}{NR_t + LE_t} \quad (52)$$

Where:

UT_t = Total project uncertainty (%)

UNR_t = Uncertainty in net emissions and removals, not including leakage (%)

ULE_t = Uncertainty in leakage emissions and losses from soil carbon stocks at time *t* (%)

NR_t = Net emissions reductions and removals at time *t*, not including leakage (tCO_2e)

LE_t = Leakage emissions and losses from soil carbon stocks at time *t* (tCO_2e)

8.4.3 Conservative Approach

Calculations of emissions reductions and removals are conservative because:

1) Baseline methane emissions use the harmonic mean for baseline emissions and an arithmetic mean for the project scenario leading to a conservative estimate for reductions in methane emissions (Section 8.1.3.1).
2) Initial baseline SOC level for modelled (activity-based) emission reductions must be the maximum of the previous 10 years, as required by the VCS rules[47, 49] . In the case of modeled approach, the baseline equilibrium SOC is set to this maximum and then compared to the modeled future equilibrium SOC (Section 8.1.3.3).
3) Because models used in the modeled approach must be validated for the project with data from the project area, no model correction is necessary. However, model predictions must meet the requirements for R^2, slope and intercept in a regression versus observed values (see section 8.1.3.3) to assure that the model does not overestimate removals. All parameter choices are to be conservative.
4) Emissions reductions are subject to reductions for uncertainty, as required by the VCS rules[47, 49] in the modeled approach, with uncertainty determined from 95 percent confidence intervals from standard errors calculated during Monte Carlo simulations (Section 8.4.2).

8.4.4 Uncertainty Deduction

If total project uncertainty in year *t*, based on 95 percent confidence intervals, $UT_t \leq$ 30 percent then no deduction must result for uncertainty.

If UT_t > 30 percent then the modified discounted value, $R_t = R_t^{disc}$ for net anthropogenic GHG removal by sinks to account for uncertainty must be:

$$R_t^{disc} = \frac{(100 - UT_t) \times R_t}{100} \tag{53}$$

Where:

R_t^{disc}	= Discounted net GHG emission reductions and removals by year *t* (tCO_2e)
UT_t	= Total project uncertainty
R_t	= Net GHG emission reductions and removals by year *t* (tCO_2e)

For *Y* years of the monitoring period,

$$R_Y = \sum_{t=1}^{d} R_t^{disc} + \sum_{t=1}^{u} R_t \tag{54}$$

Where:

d	= Number of years in which net removal must be discounted
u	= Number of years in which removals are not discounted
Y	= Number of years in the monitoring period *(d + u)*
R_t^{disc}	= Discounted net GHG emission reductions and removals by year *t* (tCO_2e)

R_t = Net GHG emission reductions and removals by year t (tCO_2e)

9 MONITORING

Given applicability conditions and allowable conservative exclusions, monitoring focuses on measuring the key parameters for calculating emissions and removals, demonstrating project management activities and measuring changes in SOC. The project activities key to changing methane emissions are altering the number and species composition of livestock grazing animals and/or species composition of forage plants , altering duration, timing, and intensity of grazing, and/or changing fire frequency, intensity and any accompanying vegetation change (such as in woody biomass). Changes in SOC density under the project scenario will also be monitored, and stratified according to management practices or soil and climatic conditions. Monitoring of soil, vegetation, grazing intensity and occurrence and intensity of fires will fully employ the permanent sampling stations discussed in Section 8.1.2.

9.1 Data and Parameters Available at Validation

9.1.1 Project Design

Data / Parameter	$PA_{m,g}$
Data unit	ha
Description	Project area in stratum m
Equations	3, 9, 11, 14 and 15
Source of data	Measured in project area
Justification of choice of data or description of measurement methods and procedures applied	Using shape files in a GIS or from known coordinates of stratum boundaries or from legal descriptions of the property included in the project area.

Comments	Project proponents must ensure that the following information in regards to the project area of each stratum is provided in the project description: 1) Map(s) of the locations of the permanent sampling plots overlaid on a map of project strata. 2) Results of cluster analysis to determine project strata. 3) Table of all project strata, their description, and area, PA_m 4) Results of analysis to determine the number of sampling units and their allocation among strata

Data Unit / Parameter	GWP_{CH4}
Data unit	t CO_2e/t CH_4
Description	Global-warming potential for CH_4
Equations	6, 8, 12, 30 and 32
Source of data	GWP_{CH4} must be obtained from the IPCC Second Assessment Report
Value applied	21
Justification of choice of data or description of measurement methods and procedures applied	
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comment	

9.1.2 Baseline Methane Emissions

Data / Parameter	$W_{c,t}$
Data unit	kg
Description	Average body weight for animals of category c in year t
Equations	1
Source of data	Measured in project area
Justification of choice of data or description of measurement methods and procedures applied	Necessary to estimate emission factor for grazing animals using allometric equations in **Error! Reference source not found.**. Measurements must be taken in accordance with the procedures described in Section 9.1.2.
Purpose of data	Calculation of baseline emissions

Comments	

Data / Parameter	$N_{c,i}$
Data unit	number
Description	Baseline number of animals of category *c* in census *i*
Equations	1
Source of data	Measured in project area
Justification of choice of data or description of measurement methods and procedures applied	The number of animals in each census *i* must be measured to calculate the harmonic mean of the multiple counts i of n censuses of animals in category c. At least four measurements within the baseline period, with at least two during the period 5-10 years prior to the project start, must be available. Measurements must be taken in accordance with the procedures described in Section 9.1.2.
Purpose of data	Calculation of baseline emissions
Comments	The project description must provide a table of historical censuses or estimates of numbers of grazing animals, BN_c, for each year in which counts or estimates are available, sorted by the k categories of animals in the project area: species, breed (if applicable), sex, and age, plus the respective live body weights (W_c) of each category, with 95% percent CI and uncertainties). The project description must also provide a data table showing calculations of methane emissions based on the equations in **Error! Reference source not found.** for each animal category for each year that data are available. The table must include calculated total emissions for that year and a cell containing the harmonic mean of total annual calculated methane emissions. This will be the baseline BEM. The harmonic mean appropriately and conservatively weights the average methane emissions towards the lower values of a time series of measurements[27]. The table must also contain the uncertainty in daily methane emissions (from the regression equations in **Error! Reference source not found.**) and the harmonic mean and its' uncertainty. Table 5 below may be used as a template.

Table 5: Table for Calculating Baseline Methane Emissions from Animal Censuses.

Grazing Animal Category					Animal Counts (Head)						Methane Emissions	
Species	Sex/Age	Weight (kg)	Annual Methane Emissions/ Animal	Per Animal Uncertainty[1]	Year 1	Year 2	Year 3	Year 4	Harmonic Mean	Uncertainty in Animal Counts	Methane Emissions for Category (tCO2e)	Uncertainty in Methane Emissions
Species 1												
Species 2												
Species 3												
Species 4												
										Total Emissions		

[1] Based on uncertainty in regression models that calculate methane emissions from body mass (see Table 3)

Species-specific weights on the left-hand side are used to calculate annual methane emissions per animal using equation 1 (section 8.1.3.1). Methane emissions per animal are then multiplied by the harmonic mean number of animals (equation 2) to estimate annual methane emissions for the animal category. Uncertainty per animal (from Table 3 in section 8.1.3.1) and uncertainty in the harmonic mean (equation 25 in section 8.4.2) combine in equation 27 to calculate overall uncertainty in methane emissions. This table must be included in the project description.

9.1.3 Parameters for Baseline Calculation of Emissions from Burning of Biomass

For projects that intend to increase fire frequency, the project description must show the equation (Equation 3) used to calculate BEBB and display a table showing estimated fire frequency $FFREQ_m$, initial unburned aboveground plant biomass ($APB_{m,b}$), with 95 percent CI and uncertainties (95 percent CI/estimate, expressed as a percentage) for each and calculated BEBB with for each project stratum.

Data / Parameter	$APB_{m,b}$
Data unit	kg dry mass/ha
Description	Mean total aboveground plant biomass in stratum m in year t at the end of the growing season (summer or wet season)
Equations	3
Source of data	Measured
Justification of choice of data or description of measurement methods and procedures applied	Measured at permanent sampling stations within each stratum *m* by clipping, drying (at 25-50 ^{o}C) and weighing aboveground vegetation from one or more small quadrats. Measured at the beginning of the dry season in the tropics or beginning of the cold or burning season in temperate climates. Must be measured in the project area 1-2 years before the project start date, or within the first year of the monitoring period and prior to the first prescribed burn if fire frequency is to be increased to manage vegetation to increase soil carbon.
Purpose of data	Calculation of baseline emissions
Comments	

Data / Parameter	$FFREQ_m$
Data unit	Dimensionless proportion
Description	Average proportion of area burned in stratum *m* in past 10 years
Equations	3
Source of data	Measured
Justification of choice of data or description of measurement methods and procedures applied	Measured by mapping burned areas with aerial photography or in projects with extensive area (> 10,000 ha), interpreting satellite images, such as MODIS, with published algorithms for assessing burned area[19]. Photography or satellite image interpretations must be verified by records of known burned areas or ground assessments of burns in the past year
Purpose of data	Calculation of baseline emissions
Comments	

Data / Parameter	BC_G
Data unit	kg biomass / kg biomass burned
Description	Baseline combustion factor for savanna/grassland
Equations	3

Source of data	Hoffa et. al., 1999 or Reference [41]
Value Applied	0.5 or default from Table 2.6, respectively
Justification of choice of data or description of measurement methods and procedures applied	It is unlikely that all aboveground biomass is combusted in fire, but this fraction is difficult to measure accurately during past years because biomass remaining after fire must be measured immediately following fire[42]. The fraction of biomass combusted usually averages around 0.75 [42] and setting BC_G = 0.5 makes the potential impact of increasing fire under the project scenario conservative in its likelihood to reduce emissions.
Purpose of data	Calculation of baseline emissions
Comments	

Data / Parameter	EF_{BG}
Data unit	g CH_4/kg biomass burned
Description	Emission factor for the burning of grassland
Equations	3, 9
Source of data	Reference [51]
Value Applied	1.9
Justification of choice of data or description of measurement methods and procedures applied	
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comments	

9.1.4 Parameters for Calculation of Baseline SOC

A critical measurement is initial soil organic carbon which is necessary in establishing the baseline SOC in the measured approach and validating the chosen soil carbon dynamic model in a modeled approach. Multiple stations must be sampled within each stratum so as to determine a 95% percent confidence interval. Some models only quantify changes in SOC to specific depths, (eg, CENTURY only predicts SOC to a depth of 20 cm[16, 31]), and if using a modeling approach with a restricted depth, the project proponents must measure depth that matches that of the model. If using a measured approach or a model that allows different soil depths to be used, and appreciable soil carbon stocks occur below 30 cm[52], then proponents are justified in sampling deeper in the soil profile, even to a depth of 1m. Known volumes of soil from the cores must be sieved to remove rocks, pebbles, and coarse fragments, and then the remainder dried (5 days at 45^{o}C or equivalent) and weighed to determine bulk density (Mg/m^3)[53].

If an IR spectrometer is to be used, the project proponent must show all calibration data in a table with spectral emissions and measurements of soils or plants and graphs showing the regressions of spectral data against measurements.

Data / Parameter	$DEPTH_{m,j,0}$
Data unit	cm
Description	Soil core depth at station *j* in stratum *m* at time *t = 0* (ie, at the start of the project or since the last verification)
Equations	4
Source of data	Measured in project area
Justification of choice of data or description of measurement methods and procedures applied	At each sampling station *j*, according to standard methods[52, 54], soil must be taken from at least 3 soil cores (with 10 cores at each site recommended to reduce uncertainty) to a depth that accounts for the vast majority (> 80 percent) of SOC in the soil column, reflects depth to hardpans or bedrock, or matches calculations from soil carbon models. Multiple cores may be well-mixed into a single composite sample for analysis.
Purpose of data	Calculation of baseline emissions
Comments	

Data / Parameter	$SOC\%_{j,m,0}$
Data unit	Dimensionless proportion
Description	Proportion soil organic carbon at station *j* in stratum *m* at time *t = 0* (ie, at the start of the project or since the last verification)
Equations	4
Source of data	Measured in project area
Justification of choice of data or description of measurement methods and procedures applied	The baseline for the measured offset approach is based on increasing SOC. Tracked at the level of j = 1 to z_m individual sampling stations in each stratum because offset will be based on demonstrating changes in SOC at individual stations and then summing increments. At each sampling station *j*, according to standard methods[52, 54], soil must be taken from at least 3 soil cores (with 10 cores at each site recommended to reduce uncertainty) to a depth that accounts for the vast majority (> 80 percent) of SOC in the soil column, reflects depth to hardpans or

	bedrock, or matches calculations from soil carbon models. Multiple cores may be well-mixed into a single composite sample for analysis. Multiple stations must be sampled within each stratum so as to determine a 95 percent confidence interval. Organic carbon concentrations must be measured in appropriate academic or industrial laboratories that use either chemical[55] combustion or appropriately calibrated spectral analysis methods. IR methods must be calibrated by regression, with $R^2 \geq 0.90$, of IR measurement with measurement by chemical or combustion methods. Graphs of regression of IR versus combustion or chemical methods must be shown. There must be no significant bias (ie, slope 95 percent confidence interval must include 1) intercept 95 percent CI must include 0. Bias must be determined by evaluating percent bias (positive or negative) following equation (5) (see detailed description of bias evaluation in Section 8.1.3.3) and cannot exceed ± 10%. If an IR spectrometer is to be used, the project proponent must show all calibration data in a table with spectral emissions and measurements of soils or plants and graphs showing the regressions of spectral data against measurements.
Purpose of data	Calculation of baseline emissions
Comments	

Data / Parameter	$BULK_{m,j,0}$
Data unit	Mg/m^3 or, equivalently, g/cm^3
Description	Bulk density at station *j* in stratum *m* at time *t = 0* (i.e., at the start of the project or since the last verification)
Equations	4
Source of data	Measured in project area
Justification of choice of data or description of measurement methods and procedures applied	At each sampling station *j*, according to standard methods[52, 54], soil must be taken from at least 3 soil cores (with 10 cores at each site recommended to reduce uncertainty) to a depth that accounts for the vast majority (> 80 percent) of SOC in the soil column, reflects depth to hardpans or bedrock, or matches calculations from soil carbon models. Multiple cores may be well-mixed into a single composite sample for analysis.

	Known volumes of soil from the cores must be sieved to remove rocks, pebbles, and coarse fragments, and then the remainder dried (5 days at 45ºC or equivalent) and weighed to determine bulk density.[53]
Purpose of data	Calculation of baseline emissions
Comments	

9.1.5 Parameters for Soil Carbon Models

Soil carbon models may require anywhere from a few to more than 80 parameters, so there is no definitive list of parameters that would apply to all models. However, in evaluating whether a modeled approach is feasible or desirable, the following parameters are likely to be key inputs into soil carbon models. Each parameter may vary among strata, depending on the size of the project area and underlying variation in soil type and plant species composition. Parameters must yield a predicted SOC density.

Data / Parameter	MAP_m
Data unit	mm/yr
Description	Mean annual precipitation in stratum m
Equations	Model input
Source of data	Precipitation maps from government or peer-reviewed published sources, nearby weather stations, or rain gauges
Justification of choice of data or description of measurement methods and procedures applied	A key variable that affects a number of processes driving SOC
Purpose of data	Calculation of baseline emissions
Comments	

Data / Parameter	$ST_{j,m,y}$
Data unit	ºC
Description	Soil temperature at station j in stratum m in month y
Equations	Model input
Source of data	Measured in project area

Justification of choice of data or description of measurement methods and procedures applied	Must be measured monthly or at least seasonally with a digital thermometer with probes inserted to at least ½ the depth at which SOC will be sampled (ie, to 10 cm if soil will be sampled and modeled to 20 cm [16])
Purpose of data	Calculation of baseline emissions
Comments	

Data / Parameter	$SAND\%_{j,m}$ and/or $CLAY\%_{j,m}$ and/or $SILT\%_{j,m}$
Data unit	Dimensionless proportion expressed as percent
Description	Proportion of soil that is sand, silt, and or clay at station j in stratum m
Equations	Model input
Source of data	Measured in project area
Justification of choice of data or description of measurement methods and procedures applied	Soil collected to desired depth at each sampling station must be mixed, and subsample analyzed for clay, silt, and sand fractions in a professional laboratory. Some models require percent sand, some percent clay and some percent of all three particle classes, sand, silt and clay.
Purpose of data	Calculation of baseline emissions
Comments	

Data / Parameter	$GI_{j,m}$
Data unit	Dimensionless proportion
Description	Mean annual grazing intensity at station j in stratum m
Equations	Model input
Source of data	Measured
Justification of choice of data or description of measurement methods and procedures applied	Measured at each sampling station prior to validation by either 1) Comparing clipped biomass at least at the end of the growing season, or more frequently for some models, inside and outside small (1 m^2) fences. $GI_{j,m}$ = 1 – (biomass outside/biomass inside). Biomass is clipped, dried at 25 – 50 ^oC, and weighed. 2) Visually estimating historical grazing intensity from a calibrated observation method (R^2>0.80 correlation between measured GI (from option 1 above and

	observational method)) based on species composition, bare ground, and vegetation height.
Purpose of data	Calculation of baseline emissions
Comments	

Data / Parameter	$MAPLC_{j,m}$
Data unit	Dimensionless proportion
Description	Mean aboveground plant cellulose plus lignin at sampling plot j in stratum m
Equations	Model input
Source of data	Measured in project area
Justification of choice of data or description of measurement methods and procedures applied	SOC is often closely related to inputs of these forms of carbon because they resist microbial decomposition.
Purpose of data	Calculation of baseline emissions
Comments	

In addition, soil carbon models will likely use fire frequency, $FFREQ_m$ introduced in Section 8.1.3.2, and initial $SOC_{m,j,0}$ introduced in Section 8.1.3.4.

Tracking parameters at each sampling station allows the chosen soil carbon model(s) to be tested at many locations and under different conditions. This improves the ability to infer whether data fit model predictions.

These parameters must be input into the chosen soil carbon model(s) to calculate the SOC parameters described below, which are used in the quantification of removals.

Data / Parameter	$MSOC_{m,j,b}$
Data unit	tC/ha
Description	Modeled SOC at station *j* in stratum *m* for each year *b* during the baseline period
Equations	7
Source of data	SOC model

Justification of choice of data or description of measurement methods and procedures applied	SOC models applied must meet with the modeling requirements described in Section 8.1.3.4.
Purpose of data	Calculation of baseline emissions
Comments	

Data / Parameter	$PSOC^{eq}_{m,j,}$
Data unit	tC/ha
Description	Modeled SOC at equilibrium at station *j* in stratum *m*
Equations	13
Source of data	SOC model
Justification of choice of data or description of measurement methods and procedures applied	SOC models applied must meet with the modeling requirements described in Section 8.2.3.3.
Purpose of data	Calculation of project emissions
Comments	

Data / Parameter	D
Data unit	years
Description	Years required to achieve SOC equilibrium
Equations	13
Source of data	SOC model
Justification of choice of data or description of measurement methods and procedures applied	SOC models applied must meet with the modeling requirements described in Section 8.2.3.
Purpose of data	Calculation of project emissions
Comments	

9.1.6 Parameters for Removals from Woody Plant Biomass

Data / Parameter	C
Data unit	kg C/kg biomass
Description	Proportion of wood composed of carbon
Equations	15
Source of data	CDM, *A/R Methodological Tool: Estimation of carbon stocks and change in carbon stocks of trees and shrubs in A/R CDM project activities*, and MacDicken, 1997
Value applied	0.45
Justification of choice of data or description of measurement methods and procedures applied	
Purpose of data	Calculation of project emissions
Comments	

9.2 Data and Parameters Monitored

Parameters monitored are those needed to calculate removals from reduced methane emissions from animals and/or removals from soil carbon sequestration plus any increases in emissions of methane from burning of biomass and leakage.

Data / Parameter	$PA_{m,t}$
Data unit	ha
Description	Project area in stratum m in year t
Equation	12, 14, 18, 19
Source of data	Measured in project area
Description of measurement methods and procedures to be applied	Using shape files in a GIS or from known coordinates of stratum boundaries or from legal descriptions of the property included in the project area.
Frequency of monitoring/recording	Annual
QA/QC procedures to be applied	Areas must be determined from accurate GIS layers of classified project area or from legal descriptions of property included in the project area. Verification should be with Global Positioning

	Systems (GPS) with an accuracy of 10 m or less. Ground points may include permanent sampling stations but also may be necessary to include points at defined stratum boundaries or along roads.
Purpose of data	Calculation of project emissions
Comments	Projects must ensure that the following information in regards to the project area of each stratum is provided within the relevant area of the project description: 1) Map(s) of the locations of the permanent sampling plots overlaid on a map of project strata. 2) Results of cluster analysis to determine project strata. 3) Table of all project strata, their description, and area, PA_m 4) Results of analysis to determine the number of sampling units and their allocation among strata

9.2.1 Project Animal Methane Emissions

Unlike when determining the baseline, the arithmetic mean of the counts during the project crediting period must be used to ensure a conservative estimate of reductions in methane emissions relative to baseline emissions, which are calculated with the harmonic mean[27].

For permissible methods of conducting an animal census, see Section 9.3.3.

Data / Parameter	$PN_{c,t}$
Data unit	number
Description	Mean number of animals of category c in the project area during year t
Equation	8, 17, 18
Source of data	Measured in project area
Description of measurement methods and procedures to be applied	Measured as the arithmetic mean of one or more years' animal censuses during the verification period
Frequency of monitoring/recording	Annual
QA/QC procedures to be applied	Based on records of livestock numbers, interviews of grazing managers, coordinators, herders or other administrative staff. Records should be kept as paper and electronic copies,

Purpose of data	Calculation of project emissions
Comments	The project description must provide a table, similar to that for calculating baseline methane emissions, of counts or estimates of numbers of grazing animals, PN_c, for each year during the monitoring period, sorted by the k categories in the project area: species, breed (if applicable), sex, and age, plus the respective live body weights (W_c) of each category, with 95% percent CI and uncertainties. The table must also contain the uncertainty in daily methane emissions and the uncertainty in the arithmetic mean count based on the equations in Section 8.4.2.2.1. Table 6 below may be use as a template.

Table 6: Table for Calculating Project Methane Emissions from Animal Censuses.

Grazing Animal Category					Animal Census (Number of Animals)						Methane Emissions	
Species	Sex/Age	Weight (kg)	Annual Methane Emissions/ Animal	Per Animal Uncertainty[1]	Year 1	Year 2	Year 3	Year 4	Arithmetic Mean	Uncertainty in Animal Counts	Methane Emissions for Category (tCO_2e)	Uncertainty in Methane Emissions
Species 1												
Species 2												
Species 3												
Species 4												
										Total Emissions		

[1] Based on uncertainty in regression models that calculate methane emissions from body mass (see Table 3)

Species-specific weights on the left-hand side are used to calculate annual methane emissions per animal using equation 1 (section 8.1.3.1). Methane emissions per animal are then multiplied by the arithmetic mean number of animals to estimate annual methane emissions for the animal category. Uncertainty per animal (from Table 3 in section 8.1.3.1) and uncertainty in the harmonic mean (equation 25 in section 8.4.2) combine in equation 27 to calculate overall uncertainty in methane emissions. This table must be included in the project description.

9.2.2 Project Emissions from Burning of Biomass

For projects that intend to increase fire frequency, the project description must show the equation (Equation (3)) used to calculate $PEBB_{m,t}$ at time *t* for each project stratum. All projects that alter fire frequency must and display a table showing estimated fire frequency $PFFREQ_{m,t}$ in year *t*, pre-fire aboveground plant biomass ($APB_{j,m,t}$), and post-fire aboveground plant biomass at stations where fire occurred ($APB_{j,m,f}$) with 95 percent CI and uncertainties for each and calculated.

Data / Parameter	$PFFREQ_{m,t}$
Data unit	Dimensionless proportion
Description	Average proportion of area burned in stratum *m* during project year t.
Equations	9
Source of data	Measured
Description of measurement methods and procedures to be applied	Measured by mapping burned areas with aerial photography or in projects with extensive area (> 10,000 ha), interpreting satellite images, such as MODIS with published algorithms for assessing burned area[19]. Photography or satellite image interpretations must be confirmed by records of known burned areas or ground assessments of burns in the past year.
Frequency of monitoring/recording	Every 15 days during the burning season
QA/QC procedures to be applied	Follow procedures in references [18, 19]
Purpose of data	Calculation of project emissions
Comments	

Data / Parameter	$APB_{j,m,t}$
Data unit	kg dry mass/ha
Description	Aboveground plant biomass at station *j* in stratum *m* in year *t* at the beginning of the dry/cold or burning season
Equations	9,10
Source of data	Measured
Description of measurement methods and procedures to be applied	Measured at permanent sampling stations within each stratum m by clipping, drying (at 25-50 ºC) and weighing aboveground vegetation from one or more small quadrats. Measurements from all quadrats must be averaged for each sampling station *j*. Measured at the beginning of the dry/cold/burning season in temperate climates[17, 56].

Frequency of monitoring/recording	Annually
QA/QC procedures to be applied	Samples must be dried in a professional drying oven for 3 days at 45-60ºC or be air-dried in sunshine for 4-7 days to a constant mass
Purpose of data	Calculation of project emissions
Comments	

Data / Parameter	$APB_{j,m,f}$
Data unit	kg dry mass/ha
Description	Aboveground plant biomass in stratum *m* in year *t* at immediately after fire
Equations	10
Source of data	Measured
Description of measurement methods and procedures to be applied	Measured at permanent sampling stations within each stratum m by clipping, drying (at 25-50 ºC) and weighing aboveground vegetation from one or more small quadrats. Measurements from all quadrats must be averaged for each sampling station *j*. Measured immediately following the occurrence of fire[17, 56].
Frequency of monitoring/recording	Once in 1-2 years prior to project start or before the first prescribed burn in the first year of the project
QA/QC procedures to be applied	Samples should be dried in a professional drying oven for 3 days at 45-60ºC or be air-dried in sunshine for 4-7 days to a constant mass
Purpose of data	Calculation of project emissions
Comments	

9.2.3 Parameters for Calculating SOC Removals

If a measured approach is taken, then the critical measurement is of SOC density at the end of the monitoring period at each sampling station, according to standard methods[52, 54]. Soil must be taken from three or more pooled soil cores (with 10 cores at each site recommended to reduce uncertainty) at each station to a desired depth (cm) For more details, see section 9.1.4

In a modeled approach, these same procedures must apply when monitoring soil carbon for the purposes of re-calibrating the chosen soil carbon model. In this case there may be a calibration period of Z years (typically 5-7 years) that is long enough to detect changes in SOC and likely longer than the monitoring periods used in a modeled approach.

Data / Parameter	$DEPTH_{m,j,t}$
Data unit	cm
Description	Soil core depth at station *j* in stratum *m* at time *t = 0* (ie, at the start of the project or since the last verification)
Equations	12
Source of data	Measured in project area
Description of measurement methods and procedures to be applied	Soil must be taken from at least three soil cores (with 10 cores at each site recommended to reduce uncertainty) at each station *j* to a depth that accounts for the vast majority (> 80 percent) of SOC in the soil column, reflects depth to hardpans or bedrock, or matches calculations from soil carbon models. Multiple cores may be well-mixed into a single composite sample for analysis.
Frequency of monitoring/recording	At the end of the monitoring period for measured approach projects, or, for modeled approach, after a desired monitoring period for re-calibrating the chosen soil carbon model on the basis of its ability to predict changes in soil carbon during the monitoring period.
QA/QC procedures to be applied	Depth cored must be the same as for baseline soil carbon sampling (see 9.1.5). However, the depth used in calculating SOC after Y years of project activities must be adjusted to account for changes in bulk density such that $DEPTH_{m,j,Y}$ x $BULK_{m,j,Y}$ = $DEPTH_{m,j,0}$ x $BULK_{m,j,0}$. This ensures that equal masses of soil are compared between year 0 and year Y
Purpose of data	Calculation of project emissions
Comments	

Data / Parameter	$SOC\%_{m,j,t}$
Data unit	Dimensionless proportion
Description	Proportion soil organic carbon at station *j* in stratum *m* at time *t*
Equations	12
Source of data	Measured in project area

Description of measurement methods and procedures to be applied	Soil must be taken from at least three soil cores (with 10 cores at each site recommended to reduce uncertainty) at each station *j* to a depth that accounts for the vast majority (> 80 percent) of SOC in the soil column, reflects depth to hardpans or bedrock, or matches calculations from soil carbon models. Multiple cores may be well-mixed into a single composite sample for analysis. The organic carbon concentrations must be measured in appropriate academic or industrial laboratories with chemical[55] automated, calibrated analytical machines or with project-area calibrated infra-red IR spectrometers[30].
Frequency of monitoring/recording	At the end of the monitoring period for measured approach projects, or, for modeled approach, after a desired monitoring period for re-validating the chosen soil carbon model on the basis of its ability to predict changes in soil carbon during the monitoring period.
QA/QC procedures to be applied	The organic carbon concentrations must be measured in appropriate academic or industrial laboratories with chemical[55] automated, calibrated analytical machines or with project-area calibrated infra-red IR spectrometers[30]. IR methods must be calibrated by regression, with $R^2 \geq 0.90$, of IR measurement with measurement by chemical or combustion methods. Graphs of regression of IR versus combustion or chemical methods must be shown. There must be no significant bias (ie, slope 95 percent confidence interval must include 1) intercept 95 percent CI must include 0, which will ensure that MBIAS, following equation (5) [37] is between -10% and +10%. If an IR spectrometer is to be used, the project proponent must show all calibration data in a table with spectral emissions and measurements of soils or plants and graphs showing the regressions of spectral data against measurements.
Purpose of data	Calculation of project emissions
Comments	

Data / Parameter	$BULK_{m,j,t}$
Data unit	Mg/m^3, or, equivalently, g/cm^3
Description	Bulk density in stratum m, station j, year t
Source of data	Measured in project area
Equations	12

Description of measurement methods and procedures to be applied	Soil must be taken from at least three soil cores (with 10 cores at each site recommended to reduce uncertainty) at each station *j* to a depth that accounts for the vast majority (> 80 percent) of SOC in the soil column, reflects depth to hardpans or bedrock, or matches calculations from soil carbon models. Multiple cores may be well-mixed into a single composite sample for analysis. Known volumes of soil from the cores must be sieved to remove rocks, pebbles, and coarse fragments, and then the remainder dried (5 days at 45ºC or equivalent) and weighed to determine bulk density.
Frequency of monitoring/recording	At the end of the monitoring period for measured approach projects, or, for modeled approach, after a desired monitoring period for re-validating the chosen soil carbon model on the basis of its ability to predict changes in soil carbon during the monitoring period.
QA/QC procedures to be applied	However, the depth used in calculating SOC after Y years of project activities must be adjusted to account for changes in bulk density such that $DEPTH_{m,j,Y}$ x $BULK_{m,j,Y}$ = $DEPTH_{m,j,0}$ x $BULK_{m,j,0}$. This ensures that equal masses of soil are compared between year 0 and year Y [53]
Purpose of data	Calculation of project emissions
Comments	

9.2.4 Parameters for Project Soil Carbon Models

If using the modeled approach, the same soil carbon model used to calculate BSOC must be used to calculate SOC expected after Y years of management under the project scenario. Uncertainties again must be calculated with Monte Carlo simulations[3, 38].

It is crucial that model input parameters must be tracked at each sampling station if possible to allow the chosen soil carbon model(s) to be most responsive to variation in major inputs to the model. The model must predict SOC density from the parameters measured and used in the model.

At verification, the project proponent must provide a list of parameters for each station under the project scenario in year t, using the VCS table format for each. These parameters will vary among models, so an exhaustive list cannot be provided. However each parameter in the model must be listed, along with its uncertainty based on a 95 percent confidence interval, so that uncertainty calculations, following the Monte Carlo procedures in 8.4.2 may be verified. For example:

Data / Parameter	$MAP_{m,Y}$

Data unit	mm/yr
Description	Mean annual precipitation in stratum m over the project crediting period Y years.
Equation	Model input
Source of data	Precipitation maps or nearby weather stations
Description of measurement methods and procedures to be applied	A key variable that affects a number of processes driving SOC
Frequency of monitoring/recording	Annually if obtained from government sources or local weather stations, Daily if collected on the project area
QA/QC procedures to be applied	Data should be obtained from government sources or local official weather stations, or, if not available, from weather data collected on the project area.
Purpose of data	Calculation of project emissions
Comments	

Data / Parameter	$ST_{j,m,Z}$
Data unit	ºC
Description	Soil temperature at station j in stratum m in month Z
Equation	Model input
Source of data	Measured in project area
Description of measurement methods and procedures to be applied	Must be measured with a digital thermometer with probes inserted to at least ½ the depth at which SOC will be sampled (ie, to 10 cm if soil will be sampled and modeled to 20 cm[3, 16])
Frequency of monitoring/recording	At least monthly
QA/QC procedures to be applied	Procedures must follow those in references [57, 58]
Purpose of data	Calculation of project emissions
Comments	

Data / Parameter	$GI_{j,m,z}$
Data unit	Dimensionless proportion
Description	Mean annual grazing intensity at station j in stratum m in year t
Equation	Model input
Source of data	Measured in project area
Description of measurement methods and procedures to be applied	Measured at each sampling station at least twice each growing season prior to verification by comparing clipped biomass at least at the end of the growing season, or more frequently for some models, inside and outside small (1 m^2) fences. GI_m = 1 – (biomass outside/biomass inside). Biomass is clipped, dried at 25 – 50 °C, and weighed.
Frequency of monitoring/recording	Must be at least twice per year, but preferably monthly, particularly in tropical project areas where plant growth can occur in any month
QA/QC procedures to be applied	Samples should be dried in a professional drying oven for 3 days at 45-60°C or be air-dried in sunshine for 4-7 days to a constant mass, following references [2, 17, 56]
Purpose of data	Calculation of project emissions
Comments	

In addition, soil carbon models for the project scenario will likely use project fire frequency, $PFFREQ_{m,t}$ or the frequency of fire (proportion area burned) in stratum m during year t (section Section 9.2.2), and initial $SOC_{m,j,0}$ introduced in Section 8.1.3.4.

9.2.5 Parameters for Project Removals from Woody Plant Biomass

The two principal parameters are the initial and verified aboveground woody plant biomasses. Uncertainty is expressed as 95% percent CI/mean for each recorded difference in biomass at each of the permanent sampling stations.

Data / Parameter	$AWPB_{m,j,0}$
Data unit	kg/ha
Description	Aboveground woody plant biomass at the project start or the year of last verification at station j and stratum m in the beginning of the monitoring period
Equations	15
Source of data	Measured in permanent sampling plots

Description of measurement methods and procedures to be applied	Circular quadrats centered at each permanent sampling station *j* must be sampled for number and diameter at breast height (dbh) of each woody stem within a specified diameter. Radius must be 5-50 cm depending on woody stem density, with smaller radii appropriate for more dense woody vegetation[45, 59].
Frequency of monitoring/recording	During the beginning of the monitoring period
QA/QC procedures to be applied	Procedures must follow those detailed in reference [46]
Purpose of data	Calculation of project emissions
Comments	

Data / Parameter	$AWPB_{m,j,Y}$
Data unit	kg/ha
Description	Aboveground woody plant biomass at station j and stratum m in year Y at the end of the monitoring period
Equations	15
Source of data	Measured in project area at permanent sampling stations
Description of measurement methods and procedures to be applied	Circular quadrats centered at each permanent sampling station *j* must be sampled for number and dbh of each woody stem within a specified diameter. Radius must be 5-50 m depending on woody stem density, with smaller radii appropriate for more dense woody vegetation[45, 59].
Frequency of monitoring/recording	Once at the end of the monitoring period
QA/QC procedures to be applied	Procedures must follow those detailed in reference [46]
Purpose of data	Calculation of project emissions
Comments	

9.2.6 Parameters for Leakage

Data / Parameter	$DN_{C,x}$
Data unit	head
Description	Number of livestock of each category *c* that were outside the project area (outside the fence defining the boundary of the

	project area, or, in the case of open grazing lands eg pastoralist areas, beyond 2 km from the mapped project area boundary on day *x*
Equations	17,18
Source of data	Measured
Description of measurement methods and procedures to be applied	Determined from records of livestock distributions, as recorded from interviews with grazing managers, coordinators, herders, or other administrative staff. For additional details see Section 9.3.3
Frequency of monitoring/recording	Monthly
QA/QC procedures to be applied	Records should be kept as paper and electronic copies
Purpose of data	Calculation of leakage
Comments	

Data / Parameter	d
Data unit	days
Description	Total number of days livestock were off the project area
Equations	17,18
Source of data	Measured
Description of measurement methods and procedures to be applied	Based on records of livestock numbers and their distribution on and off the project area, based on interviews of grazing managers, coordinators, herders or other administrative staff. For additional details see Section 9.3.3
Frequency of monitoring/recording	Monthly
QA/QC procedures to be applied	Records should be kept as paper and electronic copies, with at least one electronic copy kept off the project as an online database
Purpose of data	Calculation of leakage
Comments	

9.3 Description of the Monitoring Plan

9.3.1 Sampling Design

The sampling design of the permanent sampling stations and their division among strata is described in detail in Section 8.1.2.

9.3.2 Impact of Project Activities

Additionality of greenhouse gas reductions arises from the implementation of new management activities, and it is important for the project proponent to monitor the effectiveness of these new activities. Activities fall principally into three major categories: (1) manipulating animal numbers and grazing intensity, (2) managing fire, (3) changing plant species composition and/or lignin and cellulose content.

9.3.3 Animal Numbers

The different methods of animal censuses are reviewed by Seber[60]. The preferred methods are:

1) *Ownership records* in cases where individual records exist for each animal owned by the project proponent or participants. This is the most accurate measure of animal numbers, but is likely to only be possible in developed countries where such records can be created and maintained.

2) *Corral counts*, in which all known corrals or "bomas" where animals are kept at night are identified to category c and counted. The advantage of this method is that it allows a total census as long as all corrals can be located and censused. This may be the superior method for censusing animals kept by pastoralists in less developed countries. Care must be taken to census at times when animals are not being herded long distances to find new pasture or water, as the census may significantly underestimate animal counts. 95 percent confidence intervals may be estimated by repeated counts, comparison of counts among different observers, or subsampling methods like bootstrapping[61].

3) *Ground transect counts*, whereby transects are walked or driven and the number of animals of each category c, at distances measured with rangefinders, are counted. The area sampled by transects (length by mean observation distance) must cover at least 20 percent of the project area[60] to avoid unacceptable variance and uncertainty. Counts must be converted to density and multiplied by area to estimate total animal numbers in each category and their 95 percent confidence intervals by using the program DISTANCE[62]. Transects must be sampled in at least four years of the ten prior to the project start and at least twice per year during the project crediting period Y years. The advantage of this method is that it may be applied to wildlife or to livestock censuses in regions where livestock are not sedentary. The disadvantage is that animals are often aggregated across the landscape, which may greatly increase the variance of the

estimate, animals counted must be extrapolated to get totals for the project area, and accurate classifications of animals into categories may be inaccurate.

4) *Human surveys*, in which animal owners are interviewed about animal numbers of each category, kept in their corrals in the past. At least 30 individuals or 10 percent of the total animal holders in the project area, whichever is greater, must be interviewed. The advantage of this method is that more detail about breeds and weights may be incorporated into the determination of categories and estimation of methane emissions. The disadvantage is that the subsample of animals owned by the people interviewed must be extrapolated to encompass the project area, with accompanying uncertainty.

5) *Aerial surveys* in which animals of each category are counted from aerial photographs. This is a popular method among governments who are satisfied with broad surveys, but typically the uncertainty in aerial surveys is too large to be used with daily methane emissions, which are already plagued with relatively large uncertainties. Typically aerial surveys only work for cattle or other similarly large animals (eg, camels and horses), as sheep and goats are usually too small to be differentiated by species, sex or age from the air. Also, uncertainties for aerial surveys may be prohibitive, as they often exceed 50 percent[60].

9.3.4 Grazing Intensity

The project proponent must be prepared to measure aboveground plant biomass at least semi-annually to determine the impacts of grazing on vegetation throughout the project area. The parameter $GI_{m,j,t}$ represents the percent difference in standing crop between grazed and ungrazed (fenced) vegetation. It may be measured at all permanent sampling stations by comparing aboveground plant biomass, $APB_{j,m,t}$ at each station with biomass inside small fences (0.67 – 2 m^2). Herbaceous and shrub biomass must be clipped from three or more small quadrats at each station and from two or more small (0.67 - 2 m^2) temporary fenced quadrats (utilization cages). Grazing intensity (GI) is 1 – (biomass unfenced/biomass fenced)[17]. Cages must be moved after clipping to ensure that the station measures grazer use of plant production over each season or portion of a season. It may also be measured using calibrated satellite imagery (with at least $R^2 > 0.60$ between the satellite index and measured biomass on the ground) by comparing vegetation indices, such as NDVI or EVI[31, 63], between ungrazed and grazed pixels paired to have similar soil types, precipitation, and other variables.

9.3.5 Fire Frequency

Baseline proportion of area burned ($FFREQ_{m,b}$) and project proportion of area burned during the project crediting period Y requires demonstration of the occurrence and area covered by fires over a period of 10 years for the baseline and Y years for the project scenario. Acceptable information sources include aerial photographs or interpreted satellite images with a resolution (pixel length in m) smaller than 0.5 percent of the square root of the total project area (in m^2)[18, 19]. An example method is Dempewolf's et al. (2007)[19] algorithm, now employed as MODIS Burned

Area images dating back to 2000. These images use red and infra-red spectral information from 15 day composite images, which eliminate clouds and shadows, from MODIS satellites[12] to calculate a BAI, or burned area index that provided 85-95 percent accuracy in classifying image pixels as burned or unburned in East African grassland and savanna. Other methods of image interpretation, particularly aerial photographs, may be used. Any method must be tested by comparing pixels in classified images with observations of burned or unburned during the same time window in the permanent sampling stations. Valid interpretation methods must commit less than 12 percent combined omission and commission errors[19].

9.3.6 Plant Species Composition

A key input variable affecting soil carbon dynamics and soil carbon models is species composition, as management practices to restore soil carbon will likely do so in part by changing plant species composition[32, 64, 65]. Replacement of woody shrubs or annual grasses that dominate under baseline conditions with perennial grasses with deep root systems under the project scenario can lead to rapid carbon sequestration. Tracking plant species composition is possible by measuring aerial cover of the four most dominant species each of grasses, herbs (dicotyledonous plants, wildflowers), and woody plants. Such data can show shifts as a consequence of new management activities.

9.3.7 Plant Lignin and Cellulose

Shifts in species composition may be accompanied by shifts in plant chemical composition that greatly affect calculations of some soil carbon models and measureable soil carbon sequestration. SOC is often closely related to inputs of these forms of carbon because they resist microbial decomposition. Plant cellulose and lignin (MAPLC) may be measured by either: 1) the Van Soest method of sequential digestion of ground plant material (clipped during the measurement of aboveground plant biomass (APB)) in acid detergent and sulfuric acid[66] in a professional laboratory, or 2)with infra-red (IR) spectrometers calibrated to project area plants and soils.

9.3.8 Ex Ante Leakage and Other Emission Sources

Leakage is mainly possible from net transfers of livestock out of the project area, which is not allowed by the applicability conditions but nevertheless must be monitored by inventorying livestock shipping depots and from censuses and interviews with inhabitants of the project area. Close monitoring and census efforts are especially needed during dry seasons or other periods when there may be strong motivation to move animals off the project area. Animal censuses must be timed to coincide with the greatest risk of animal movement to have the greatest chance to track any possible leakage.

[12] http://modis.gsfc.nasa.gov/

The possible but unlikely source of new emissions as a result of the project is the increase in the use of fossil fuels during vehicle and airplane use associated with management activities. These may be tracked with mileage logs in all project and associated vehicles and converted with IPCC 2000 emission factors[67] as stratified by the type of vehicle and fuel type (eg, diesel, gasoline, kerosene), to determine whether fossil fuel use approaches being a significant greenhouse gas source associated with project activity.

2 SUMMARY DESCRIPTION OF THE METHODOLOGY

Additionality and Crediting Method	
Additionality	Projects located within the United States: Activity method Projects located outside the United States: Project method
Crediting Baseline	Project method

Wetland restoration occurs sporadically throughout the world primarily to create wildlife habitat, restore water quality and quantity levels and provide storm protection and food production. However, wetland restoration also provides the additional benefits of greenhouse gas (GHG) emission reductions and climate change mitigation.

This methodology outlines procedures to estimate net greenhouse gas emission reductions and removals resulting from project activities implemented to restore tidal wetlands. Such activities may include creating, restoring, and/or managing hydrological conditions, sediment supply, salinity characteristics, water quality and/or native plant communities. Accordingly, this methodology is applicable to a wide range of project activities aimed at restoring and creating tidal wetlands, and emission reductions and removals are estimated primarily based on the ecological changes that occur as a result of such activities (eg, increased vegetative cover, changes to water table depth).

This methodology also addresses the potential for the establishment of woody vegetation. As such, this methodology is categorized as a Restoring Wetland Ecosystems (RWE) and Afforestation, Reforestation and Revegetation (ARR) methodology.

Project activities are expected to generate GHG emission reductions and removals through:

- Increased biomass
- Increased autochthonous soil organic carbon
- Reduced methane and/or nitrous oxide emissions due to increased salinity or changing land use
- Reduced carbon dioxide emissions due to avoided soil carbon loss

This methodology is applicable to projects located anywhere in the world, and to all tidal wetland systems (ie, tidal forests (such as mangroves), tidal marshes and seagrass meadows). An activity method is used for the additionality assessment of projects located in the United States, and a project method is used for the additionality assessment of projects located outside the United States. A project method is used with respect to the crediting baseline for all projects.

For strata with organic soil, this methodology sets out procedures for the estimation of peat depletion time (PDT). Likewise, for strata with mineral soils and sediments, this methodology provides procedures for the estimation of soil organic carbon depletion time (SDT). This methodology also includes an assessment of the maximum quantity of GHG emission reductions which may be claimed from the soil organic carbon (SOC) pool (either on the basis of the difference between the remaining soil organic carbon stock in the project and baseline scenarios after 100 years (total stock approach), or the difference in cumulative carbon loss in both scenarios since the project start date (stock loss approach)).

In order to estimate carbon stock changes in tree and shrub biomass, this methodology uses procedures from CDM tool *AR-Tool14 Estimation of carbon stocks and change in carbon stocks of trees and shrubs in A/R CDM project activities*. This methodology also provides a method to account for carbon stock changes in herbaceous vegetation.

Since biomass may be lost due to subsidence following sea level rise, restoration projects involving afforestation or reforestation may account for long-term carbon storage in wood products where trees are harvested before dieback.

GHG emissions from the SOC pool are estimated by assessing emissions of CO_2, CH_4 and N_2O, which may be estimated via several methods (eg, proxies, modeling, default factors, local published values). Where allochthonous SOC accumulates in the project scenario, a procedure is provided to deduct such carbon from net emission reductions.

Proxies for emissions from the SOC pool may include water table depth and soil subsidence (for which procedures from other methodologies and modules are used) and carbon stock change. For non-seagrass tidal wetland systems, a default factor may be used in the absence of local data.

CH_4 emissions in the baseline scenario may be conservatively set to zero. Where the project proponent demonstrates that N_2O emissions do not increase in the project scenario compared to the baseline scenario, N_2O emissions need not be accounted for either. In all cases, N_2O emissions may be conservatively excluded in the baseline scenario.

This methodology also addresses anthropogenic peat fires occurring in drained areas, and establishes a conservative default value (*Fire Reduction Premium*) based on fire occurrence and extension in the project area in the baseline scenario. The procedure is based on VCS module *VMD0046 Methods for monitoring soil carbon stock changes and GHG emissions in WRC project activities.* The approach avoids the direct assessment of GHG emissions from fire in the baseline and project scenarios.

This methodology also includes procedures to account for GHG emissions from prescribed burning (using literature-based emission factors for non-CO_2 GHGs) and fossil fuel use (by incorporating procedures from the CDM tool *Estimation of GHG emissions related to fossil fuel combustion in A/R CDM project activities*).

This methodology includes procedures for the consideration of sea level rise with respect to determining the geographic boundaries of the project area, and the determination of the baseline scenario and baseline emissions.

Activity-shifting leakage and market leakage are deemed not to occur if the applicability conditions of this methodology are met. Furthermore, activity-shifting leakage and market leakage are deemed not to occur if the pre-project land use will continue during the project crediting period.

Under the applicability conditions of this methodology, ecological leakage does not occur by ensuring that the effect of hydrological connectivity with adjacent areas is insignificant (ie, no alteration of mean annual water table depths will occur in such areas). In tidal wetland restoration projects, de-watering downstream wetlands is not expected.

This methodology provides the steps necessary for estimating the project's net GHG benefits, as represented by the equation below:

$$NER_{RWE} = GHG_{BSL} - GHG_{WPS} + FRP - GHG_{LK}$$

Where:

NER_{RWE}	Net CO_2e emission reductions from the RWE project activity
GHG_{BSL}	Net CO_2e emissions in the baseline scenario
GHG_{WPS}	Net CO_2e emissions in the project scenario
FRP	*Fire Reduction Premium* (net CO_2e emission reductions from organic soil combustion due to rewetting and fire management)
GHG_{LK}	Net CO_2e emissions due to leakage

3 DEFINITIONS

In addition to the definitions set out in VCS document *Program Definitions*, the following definitions apply to this methodology:

Allochthonous Soil Organic Carbon
Soil organic carbon originating outside the project area and being deposited in the project area

Autochthonous Soil Organic Carbon
Soil organic carbon originating or forming in the project area (eg, from vegetation)

Degraded wetland
A wetland which has been altered by human or natural impact through the impairment of physical, chemical and/or biological properties, and in which the alteration has resulted in a reduction of the diversity of wetland-associated species, soil carbon or the complexity of other ecosystem functions which previously existed in the wetland

Impounded Water
A pool of water formed by a dam or pit

Marsh
A subset of wetlands characterized by emergent soft-stemmed vegetation adapted to saturated soil conditions[1]

Mineral Soil
Soil that is not organic

Mudflat
A subset of tidal wetlands consisting of soft substrate not supporting emergent vegetation

Open Water
An area in which water levels do not fall to an elevation that exposes the underlying substrate

---

[1] There are many different kinds of marshes, ranging from the prairie potholes to the Everglades, coastal to inland, freshwater to saltwater, but the scope of this methodology is limited to tidal marshes. Salt marshes consist of salt-tolerant and dwarf brushwood vegetation overlying mineral or organic soils.

Organic Soil

Soil with a surface layer of material that has a sufficient depth and percentage of organic carbon to meet thresholds set by the IPCC (Wetlands supplement) for organic soil. Where used in this methodology, the term peat is used to refer to organic soil.

Salinity Average

The average water salinity value of a wetland ecosystem used to represent variation in salinity during periods of peak CH_4 emissions (eg, during the growing season in temperate ecosystems)

Salinity Low Point

The minimum water salinity value of a wetland ecosystem used to represent variation in salinity during periods of peak CH_4 emissions (eg, during the growing season in temperate ecosystems)

Seagrass Meadow

An accumulation of seagrass plants over a mappable area[2]

Tidal Wetland

A subset of wetlands under the influence of the wetting and drying cycles of the tides (eg, marshes, seagrass meadows, tidal forested wetlands and mangroves). Sub-tidal seagrass meadows are not subject to drying cycles, but are still included in this definition.

Tidal Wetland Restoration

Restoration of degraded tidal wetlands in which establishment of prior ecological conditions is not expected to occur in the absence of the project activity. For the purpose of this methodology, this definition also includes activities that create wetland ecological conditions on mudflats or within open or impounded water.

Water Table Depth

Depth of sub-soil or above-soil surface of water, relative to the soil surface

---

[2] This definition includes both the biotic community and the geographic area where the biotic community occurs. Note that the vast majority of seagrass meadows are sub-tidal, but a percentage are intertidal.

4 APPLICABILITY CONDITIONS

This methodology applies to tidal wetland restoration project activities (*tidal wetland restoration* as defined in Section 3 above).

This methodology is applicable under the following conditions:

1) Project activities which restore tidal wetlands (including seagrass meadows, per this methodology's definition of *tidal wetland*) are eligible.
2) Project activities may include any of the following, or combinations of the following:
    a) Creating, restoring and/or managing hydrological conditions (eg, removing tidal barriers, improving hydrological connectivity, restoring tidal flow to wetlands or lowering water levels on impounded wetlands)
    b) Altering sediment supply (eg, beneficial use of dredge material or diverting river sediments to sediment-starved areas)
    c) Changing salinity characteristics (eg, restoring tidal flow to tidally-restricted areas)
    d) Improving water quality (eg, reducing nutrient loads leading to improved water clarity to expand seagrass meadows, recovering tidal and other hydrologic flushing and exchange, or reducing nutrient residence time)
    e) (Re-)introducing native plant communities (eg, reseeding or replanting)
    f) Improving management practice(s) (eg, removing invasive species, reduced grazing)
3) Prior to the project start date, the project area:
    a) Is free of any land use that could be displaced outside the project area, as demonstrated by at least one of the following, where relevant:
        i) The project area has been abandoned for two or more years prior to the project start date; or
        ii) Use of the project area for commercial purposes (ie, trade) is not profitable as a result of salinity intrusion, market forces or other factors. In addition, timber harvesting in the baseline scenario within the project area does not occur; or
        iii) Degradation of additional wetlands for new agricultural sites within the country will not occur or is prohibited by enforced law.

    OR

    b) Is under a land use that could be displaced outside the project area (eg, timber harvesting), though in such case emissions from this land use shall not be accounted for.

    OR

    c) Is under a land use that will continue at a similar level of service or production during the project crediting period (eg, reed or hay harvesting, collection of fuelwood, subsistence harvesting).

The project proponent must demonstrate (a), (b) or (c) above based on verifiable information such as laws and bylaws, management plans, annual reports, annual accounts, market studies, government studies or land use planning reports and documents.

4) Live tree vegetation may be present in the project area, and may be subject to carbon stock changes (eg, due to harvesting) in both the baseline and project scenarios.

5) The prescribed burning of herbaceous and shrub aboveground biomass (cover burns) as a project activity may occur.

6) Where the project proponent intends to claim emission reductions from reduced frequency of peat fires, project activities must include a combination of rewetting and fire management.

7) Where the project proponent intends to claim emission reductions from reduced frequency of peat fires, it must be demonstrated that a threat of frequent on-site fires exists, and the overwhelming cause of ignition of the organic soil is anthropogenic (eg, drainage of the peat, arson).

8) In strata with organic soil, afforestation, reforestation, and revegetation (ARR) activities must be combined with rewetting.

This methodology is not applicable under the following conditions:

9) Project activities qualify as IFM or REDD.

10) Baseline activities include commercial forestry.

11) Project activities lower the water table, unless the project converts open water to tidal wetlands, or improves the hydrological connection to impounded waters.

12) Hydrological connectivity of the project area with adjacent areas leads to a significant increase in GHG emissions outside the project area.

13) Project activities include the burning of organic soil.

14) Nitrogen fertilizer(s), such as chemical fertilizer or manure, are applied in the project area during the project crediting period.

5 PROJECT BOUNDARY

5.1 Temporal Boundaries

5.1.1 Peat depletion time (PDT)

Projects that do not quantify reductions of baseline emissions (ie, those which limit their accounting to GHG removals in biomass and/or soil) need not estimate PDT.

PDT ($t_{PDT\text{-}BSL,i}$) for a stratum in the baseline scenario equals the period during which the project is eligible to claim emission reductions from rewetting, and is estimated at the project start date for each stratum *i* as:

$$t_{PDT\text{-}BSL,i} = Depth_{peat,i,t0} / Rate_{peatloss\text{-}BSL,i} \quad \textbf{(1)}$$

Where:

$t_{PDT\text{-}BSL,i}$	PDT in the baseline scenario in stratum *i* (in years elapsed since the project start date); yr
$Depth_{peat,i,t0}$	Average organic soil depth above the drainage limit in stratum *i* at the project start date; m
$Rate_{peatloss\text{-}BSL,i}$	Rate of organic soil loss due to subsidence and fire in the baseline scenario in stratum *i*; m yr^{-1}.
i	1, 2, 3 …M_{BSL} strata in the baseline scenario

If $t_{PDT\text{-}BSL,i}$ falls within the crediting period, subsequent organic carbon loss from remaining mineral soil may be estimated as well using the procedure for SDT in Section 5.1.2.

Organic soil depths, depths of burn scars and subsidence rates must be derived from the data sources described in Section 9.1.

5.1.2 Soil organic carbon depletion time (SDT)

Projects that do not quantify reductions of baseline emissions (ie, those which limit their accounting to GHG removals in biomass and/or soil) need not estimate SDT.

SDT ($t_{SDT\text{-}BSL,i}$) for a stratum in the baseline scenario equals the period during which the project is eligible to claim emission reductions from restoration, and is estimated at the project start date for each stratum *i* as:

$$t_{SDT\text{-}BSL,i} = C_{,i,t0} / Rate_{Closs\text{-}BSL,i} \quad \textbf{(2)}$$

Where:

$t_{SDT\text{-}BSL,i}$	SDT in the baseline scenario in stratum *i* (in years elapsed since the project start date); yr
$C_{i,t0}$	Average organic carbon stock in mineral soil in stratum *i* at the project start date; t C ha^{-1} (see Equation 11)
$Rate_{Closs\text{-}BSL,i}$	Rate of organic soil carbon loss due to oxidation in the baseline scenario in stratum *i*; t C ha^{-1} yr^{-1}.
i	1, 2, 3 …M_{BSL} strata in the baseline scenario

The project proponent must determine the depth ($Depth_{soil,i,t0}$ in Equation 11 below) over which $C_{,i,t0}$ is determined. Note that a shallower depth will lead to a shorter, and more conservative, SDT. Where SDT is not determined, no reductions of baseline emissions from mineral soil may be claimed.

Extrapolation of $Rate_{Closs\text{-}BSL,i}$ over the project crediting period must account for the possibility of a non-linear decrease of soil organic carbon over time, including the tendency of organic carbon concentrations to approach steady-state equilibrium. For this reason, a complete loss of soil organic carbon may not occur in mineral soils. This steady-state equilibrium must be determined conservatively.

In case of alternating mineral and organic horizons, $Rate_{Closs\text{-}BSL,i}$ may be determined for all individual horizons. This also applies to cases where an organic surface layer of less than 10 cm exists or in cases where the soil is classified as organic but its organic matter depletion is expected within the project crediting period and oxidation of organic matter in an underlying mineral soil may occur within this period.

SDT is conservatively set to zero for project sites drained more than 20 years prior to the project start date. SDT is also conservatively set to zero where significant soil erosion occurs in the baseline scenario (*significant* defined as >5 percent of $Rate_{Closs\text{-}BSL,i}$).

With respect to the estimation of SDT, the accretion of sediment in the baseline scenario is conservatively excluded.

5.2 Geographic Boundaries

5.2.1 General

The project proponent must define the geographic boundaries of the project area at the beginning of project activities. The project proponent must provide the geographic coordinates of lands (including sub-tidal seagrass areas, where relevant) included in the project area to facilitate accurate delineation of the project area. Remotely-sensed data, published topographic maps and data, land administration and tenure records and/or other official documentation that facilitates clear delineation of the project area must be used.

The project activity may contain more than one discrete area of land. Each discrete area of land must have a unique geographical identification.

When describing physical project boundaries, the following information must be provided for each discrete area:

- Name of the project area (including compartment numbers, local name (if any)).
- Unique identifier for each discrete parcel of land.
- Map(s) of the area (preferably in digital format).
- The project area must be geo-referenced, and provided in digital format in accordance with VCS rules.

- Total area.
- Details of land rights holder and user rights.

5.2.2 Stratification

Where the project area at the project start date is not homogeneous, stratification may be carried out to improve the accuracy and the precision of carbon stock and GHG flux estimates. Where stratification is employed, different stratifications may be required for the baseline and project scenarios in order to achieve optimal accuracy of the estimates of net GHG emission reductions and removals.

Strata may be defined based on soil type and depth (including eligibility as assessed below), water table depth, vegetation cover and/or vegetation composition, salinity, land type (open water, channel, and unvegetated sand or mudflat) or expected changes in these characteristics.

Strata must be spatially discrete and stratum areas must be known. Areas of individual strata must sum to the total project area. Strata must be identified with spatial data (eg, maps, GIS coverage, classified imagery, sampling grids) from which the area can be determined accurately. Land use/land cover maps in particular must be ground-truthed and less than 10 years old, unless it can be demonstrated that the maps are still accurate. Strata must be discernible taking into account good practice with respect to accuracy requirements for the definition of strata limits and boundaries. The type of spatial data must be indicated and justified in the project description.

The project area may be stratified *ex ante*, and this stratification may be revised *ex post* for monitoring purposes. Established strata may be merged if reasons for their separate establishment are no longer meaningful, or have proven irrelevant to key variables for estimating net GHG emission reductions and removals. Baseline stratification must remain fixed until a reassessment of the baseline scenario occurs. Stratification in the project scenario must be reviewed at each monitoring event prior to verification and revised if necessary.

The sub-sections below specify further requirements and guidance with respect to stratification in certain scenarios.

<u>Areas with organic soil</u>

The project proponent must use VCS module *VMD0016 Methods for Stratification of the Project Areas* in order to stratify project areas that include organic soil.

<u>Seagrass meadows</u>

Given the tendency of seagrasses to respond differently under different light and depth regimes, the project proponent may differentiate between seagrass meadow sections that occur at different depths given discrete, or relatively abrupt, bathymetric and substrate changes.

For seagrass meadow restoration projects in areas with existing seagrass meadows, the project proponent must quantify the percentage of meadow expansion that can be attributed to the restoration effort but that is not the result of direct planting or seeding. Existing meadows (unless smaller in area than 5 percent of the total project area) must be excluded from the calculation of project emissions, even in cases where the restored meadow enhances carbon sequestration rates in existing meadows.

New seagrass meadows that result from natural expansion must be contiguous with restored meadow plots in order to be included in project accounting, unless the project proponent demonstrates that non-contiguous meadow patches originated from restored meadow seeds. This may be performed via genetic testing, or estimated as a percentage of new meadow in non-contiguous plots and observed no less than four years after the project start date.[3] This percentage must not exceed the proportion of restored meadow area relative to the total seagrass meadow areal extent, and the project proponent must demonstrate the feasibility of current-borne seed dispersal from the restored meadow. In cases where a restored meadow coalesces with an existing meadow(s), the project proponent must delineate the line at which the two meadows are joined. The project proponent may use either aerial observations showing meadow extent or direct field observations.

Native ecosystems

In order to claim emission removals from ARR or WRC activities, the project proponent must provide evidence in the project description that the project area was not cleared of native ecosystems to create GHG credits. Such proof is not required where such clearing took place prior to the 10-year period prior to the project start date. Areas that do not meet this requirement must be excluded from the project area.

Stratification of vegetation cover for adoption of the default SOC accumulation rate

The default factor for SOC accumulation rate (see Sections 8.1.4.2.3 and 8.2.4.2.1) may only be applied to non-seagrass tidal wetland systems with a crown cover of at least 50 percent. Areas below this threshold must be marked and excluded from the application of the default SOC accumulation rate. For the baseline scenario, crown covers must be based on a time series of vegetation composition. For the project scenario, crown cover mapping must be performed according to established methods in scientific literature.

Stratification of salinity for the accounting of CH_4

Tidal wetlands may be stratified according to salinity for the purpose of estimating CH_4 emissions. Threshold values of salinity for mapping salinity strata are specified in Section 8.1.4.4.4.

Areas with unrestricted tidal exchange will maintain salinity levels similar to the tidal water source, while those with infrequent tidal flooding will not (in which case the use of channel water salinity

---

[3] McGlathery *et al.* (2012)

levels is not reliable). For such areas it is therefore recommended to stratify according to the frequency of tidal exchange.

Procedures for the measurement of salinity levels are specified in Section 9.3.8.

Stratification of water bodies lacking tidal exchange

The area of ponds, ditches or similar bodies of water within the project area must be measured and treated as separate strata when they do not have surface tidal water exchange. CH_4 emissions from these features may be excluded from GHG accounting if the area of these features does not increase in the project scenario.

5.2.3 Sea level rise

When defining geographic project boundaries and strata, the project proponent must consider expected relative sea level rise and the potential for expanding the project area landward to account for wetland migration, inundation and erosion.

For both the baseline and project scenarios, the project proponent must provide a projection of relative sea level rise within the project area based on IPCC regional forecasts or peer-reviewed literature applicable to the region. In addition, the project proponent may also utilize expert judgment[4]. Global average sea level rise scenarios are not suitable for determining changes in wetlands boundaries. Therefore, if used, IPCC most-likely global sea level rise scenarios must be appropriately downscaled to regional conditions including vertical land movements, such as subsidence.

Whether degradation occurs in the baseline scenario or restoration occurs in the project scenario, the assessment of potential wetland migration, inundation and erosion with respect to projected sea level rise must account for topographical slope, land use and management, sediment supply and tidal range. The assessment may use literature relevant to the project area, expert judgment or both.

The potential for tidal wetlands to migrate horizontally must consider the topography of the adjacent land and any migration barriers that may exist. In general, and on coastlines where wetland migration is unimpaired by infrastructure, concave-up slopes may cause ‘coastal squeeze’, while straight or convex-up gradients are more likely to provide the space required for lateral movement.

The potential for tidal wetlands to rise vertically with sea level rise is sensitive to suspended sediment loads in the system. A sediment load of >300 mg per liter has been found to balance high-end IPCC scenarios for sea level rise (Orr *et al*. 2003, Stralsburg *et al*. 2011). French (2006) and Morris *et al*. (2012) suggest that the findings of Orr *et al*. 2003 based in the San Francisco

[4] Requirements for expert judgment are provided in Section 9.3.3.

Bay could be used elsewhere. French (2006) indicates that at 250 mg per liter, sea level rise of 15 mm is balanced at a tidal range of 1 m or greater. Therefore, for marshes with a tidal range greater than 1 meter, the project proponent may use >300 mg per liter as a sediment load threshold above which wetlands are not predicted to be submerged. The project proponent may use lower threshold values for tidal range and sediment load where justified. The vulnerability of tidal wetlands to sea level rise and conversion to open water is also related to tidal range. In general, the most vulnerable tidal wetlands are those in areas with a small tidal range, those with elevations low in the tidal frame and those in locations with low suspended sediment loads.

Alternatively, in the project scenario the project proponent may conservatively assume that part of the wetland within the project area erodes, and does not migrate. In the baseline scenario, the project proponent may conservatively assume that part of the project area submerges, with reduced emissions as a consequence.

The projection of wetland boundaries within the project area must be presented in maps delineating these boundaries from the project start date until the end of the project crediting period, at intervals appropriate to the rate of change due to sea level rise, and at t = 100.

Procedures for accounting for project area submergence due to relative sea level rise are provided in Section 8.2.2.

5.2.4 Ineligible wetland areas

For projects quantifying CO_2 emission reductions, project areas which do not achieve a significant difference (≥ 5 percent) in cumulative carbon loss over a period of 100 years beyond the project start date are not eligible for crediting based on the reduction of baseline emissions, and these areas must be mapped.

The maximum quantity of GHG emission reductions which may be claimed from the soil carbon pool is limited to the difference between the remaining soil organic carbon stock in the project and baseline scenarios after 100 years (total stock approach), or the difference in cumulative soil organic carbon loss in both scenarios over a period of 100 years since the project start date (stock loss approach). The project proponent must calculate this maximum quantity *ex ante* using conservative parameters, and following one of the options below.

1. Total stock approach

The difference between soil organic carbon stock in the project scenario and baseline scenario at t = 100 is estimated as:

$$C_{WPS-BSL,t100} = \sum_{i=1}^{M_{WPS}} \left(C_{WPS,i,t100} \times A_{WPS,i} \right) - \sum_{i=1}^{M_{BSL}} \left(C_{BSL,i,t100} \times A_{BSL,i} \right) \quad \textbf{(3)}$$

$C_{WPS,i,t100}$ requires no adjustment for leakage since the applicability conditions of this methodology are structured to ensure leakage emissions do not occur, as explained in Section 8.3.

The difference between organic carbon stock in the project scenario and baseline scenario at t = 100 ($C_{WPS\text{-}BSL,t100}$) is significant if:

$$\sum_{i=1}^{M_{WPS}} \left(C_{WPS,i,t100} \times A_{WPS,i} \right) \geq 1.05 \times \sum_{i=1}^{M_{BSL}} \left(C_{BSL,i,t100} \times A_{BSL,i} \right) \quad (4)$$

For organic soil:

$$C_{WPS,i,t100} = Depth_{peat\text{-}WPS,i,t100} \times VC \times 10 \quad (5)$$

$$C_{BSL,i,t100} = Depth_{peat\text{-}BSL,i,t100} \times VC \times 10 \quad (6)$$

$$Depth_{peat-BSL,i,t100} = Depth_{peat,i,t0} - \sum_{t=1}^{t=100} Rate_{peatloss-BSL,i,t} \quad (7)$$

$$Depth_{peat-WPS,i,t100} = Depth_{peat,i,t0} - \sum_{t=1}^{t=100} Rate_{peatloss-WPS,i,t} \quad (8)$$

For mineral soil:

$$C_{BSL,i,t100} = C_{i,t0} - \sum_{t=1}^{t=100} Rate_{Closs-BSL,i,t} \quad (9)$$

$$C_{WPS,i,t100} = C_{i,t0} - \sum_{t=1}^{t=100} Rate_{Closs-WPS,i,t} \quad (10)$$

$$C_{i,t0} = Depth_{soil,i,t0} \times VC \times 10 \quad (11)$$

Where a conservative constant rate of subsidence or carbon loss is applied, a possible negative outcome must be substituted by zero.

The carbon content of organic or mineral soil may be taken from measurements within the project area, or from literature involving the project area or similar areas.

2. Stock loss approach

The project proponent may also calculate the maximum quantity based on cumulative soil organic carbon loss up to t = 100 as follows:

$$C_{WPS-BSL,t100} = \sum_{i=1}^{M_{BSL}} \left(C_{loss-BSL,i,t100} \times A_{BSL,i} \right) - \sum_{i=1}^{M_{WPS}} \left(C_{loss-WPS,i,t100} \times A_{WPS,i} \right) \quad \textbf{(12)}$$

For organic soil:

$$C_{loss-BSL,i,t100} = 10 \times \sum_{t=1}^{100} \left(Rate_{peatloss-BSL,i,t} \times VC \right) \quad \textbf{(13)}$$

$$C_{loss-WPS,i,t100} = 10 \times \sum_{t=1}^{100} \left(Rate_{peatloss-WPS,i,t} \times VC \right) \quad \textbf{(14)}$$

For mineral soil:

$$C_{loss-BSL,i,t100} = 10 \times \sum_{t=1}^{100} \left(Rate_{Closs-BSL,i,t} \times VC \right) \quad \textbf{(15)}$$

$$C_{loss-WPS,i,t100} = 10 \times \sum_{t=1}^{100} \left(Rate_{Closs-WPS,i,t} \times VC \right) \quad \textbf{(16)}$$

Where:

$C_{WPS-BSL,i,t100}$	Difference between soil organic carbon stock in the project scenario and baseline scenario in subsidence stratum *i* at *t* = 100; t C ha^{-1}
$C_{WPS,i,t100}$	Soil organic carbon stock in the project scenario in stratum *i* at *t* = 100 ; t C ha^{-1}
$C_{BSL,i,t100}$	Soil organic carbon stock in the baseline scenario in stratum *i* at *t* = 100; t C ha^{-1}
$A_{WPS,i}$	Area of project stratum *i*; ha
$A_{BSL,i}$	Area of baseline stratum *i*; ha
$Depth_{peat-WPS,i,t100}$	Average organic soil depth in the project scenario in stratum *i* at *t* = 100; m
$Depth_{peat-BSL,i,t100}$	Average organic soil depth in the baseline scenario in stratum *i* at *t* = 100; m
VC	Volumetric organic carbon content in organic or mineral soil; kg C m^{-3}
$Depth_{peat,i,t0}$	Average organic soil depth above the drainage limit in stratum *i* at the project start date; m
$Rate_{peatloss-BSL,i,t}$	Rate of organic soil loss due to subsidence and fire in the baseline scenario in stratum *i* in year *t*; m yr^{-1}.
$Rate_{peatloss,WPS,i,t}$	Rate of organic soil loss due to subsidence in the project scenario in stratum *i* in year *t*; m yr^{-1}.
$C_{i,t0}$	Soil organic carbon stock in mineral soil in stratum *i* at the project start date; t C ha^{-1}

$Rate_{Closs\text{-}BSL,i,t}$	Rate of organic carbon loss in mineral soil due to oxidation in the baseline scenario in stratum *i* in year *t*; t C ha^{-1} yr^{-1}.
$Rate_{Closs,WPS,i,t}$	Rate of organic carbon loss in mineral soil due to oxidation in the project scenario in stratum *i* in year *t*; t C ha^{-1} yr^{-1}. This value is conservatively set to zero as loss rates are likely to be negative. This parameter must be reassessed when the baseline is reassessed.
$Depth_{soil,i,t0}$	Mineral soil depth in stratum *i* at the project start date (as in Equation 11); m
$C_{loss\text{-}BSL,i,t100}$	Cumulative soil organic carbon loss in the baseline scenario in stratum *i* at *t* = 100; t C ha^{-1}
$C_{loss\text{-}WPS,i,t100}$	Cumulative soil organic carbon loss in the project scenario in stratum *i* at *t* = 100; t C ha^{-1}
i	1, 2, 3 …M_{BSL} strata in the baseline scenario
t_{100}	100 years after the project start date

5.2.5 Buffer zones

Where established, buffer zones must be mapped in accordance with the VCS rules.

5.3 Carbon Pools

The carbon pools included in and excluded from the project boundary are shown in Table 5.1 below.

Carbon pools may be deemed *de minimis* and do not need to be accounted for if together the omitted decrease in carbon stocks or increase in GHG emissions (Table 5.2) amounts to less than 5 percent of the total GHG benefit generated by the project. Peer reviewed literature or the CDM tool *Tool for testing significance of GHG emissions in A/R CDM project activities* may be used to determine whether decreases in carbon pools are *de minimis*.

Table 5.1 Selection and justification of carbon pools

Carbon Pool	Included?	Justification/Explanation
Above-ground tree biomass	Yes	Major carbon pool may significantly increase or decrease in both the baseline and project scenarios, in the case of establishment or presence of tree vegetation. Above-ground tree biomass in the baseline scenario must be included. Above-ground tree biomass in the project scenario may be included or conservatively omitted.
Above-ground non-tree biomass	Yes	Carbon stock in this pool may increase in the baseline scenario and may increase or decrease in the project scenario.

Below-ground biomass	Yes	Major carbon pool may significantly increase in the baseline, or decrease in the project, or both, in case of presence of tree vegetation. Below-ground biomass in the baseline scenario must be included. Below-ground biomass in the project scenario may be included or conservatively omitted.
Litter	No	This pool is optional for WRC methodologies. Litter is only included indirectly in association with the quantification of herbal mass.
Dead wood	No	This pool is optional for WRC methodologies.
Soil	Yes	The soil organic carbon stock may increase due to the implementation of the project activity.
Wood products	Yes	Carbon stock in this pool may increase in the project scenario.

5.4 Sources of Greenhouse Gases

The greenhouse gases included in or excluded from the project boundary are shown in Table 5.2 below.

GHG sources may be deemed *de minimis* and do not have to be accounted for if together the omitted decrease in carbon stocks (Table 5.1) or increase in GHG emissions amounts to less than 5 percent of the total GHG benefit generated by the project. Peer-reviewed literature or the CDM tool *Tool for testing significance of GHG emissions in A/R CDM project activities* may be used to determine whether increases in emissions are *de minimis*.

Table 5.2 GHG Sources Included In or Excluded From the Project Boundary

Source		Gas	Included?	Justification/Explanation
Baseline	The production of methane by microbes	CH_4	Yes	May be conservatively excluded in the baseline scenario.
	Denitrification/nitrification	N_2O	Yes	May be conservatively excluded in the baseline scenario.
	Burning of biomass and organic soil	CO_2	Yes	Implicitly included in the *Fire Reduction Premium* approach.
		CH_4	Yes	Implicitly included in the *Fire Reduction Premium* approach.
		N_2O	Yes	Implicitly included in the *Fire Reduction Premium* approach.
	Fossil fuel use	CO_2	Yes	May be conservatively excluded in the baseline scenario.
		CH_4	No	Conservatively excluded in the baseline scenario.
		N_2O	No	Conservatively excluded in the baseline scenario.
Project	The production of methane by microbes	CH_4	Yes	Potential major source of emissions in the project in low salinity and freshwater areas.
	Denitrification/nitrification	N_2O	Yes	May increase as a result of the project activity.
	Burning of biomass	CO_2	No	CO_2 is addressed in carbon stock change procedures.
		CH_4	Yes	Potential major source of fire emissions.
		N_2O	Yes	Potential major source of fire emissions.
	Fossil fuel use	CO_2	Yes	Potential major source of emissions in project scenario.
		CH_4	No	Not a significant source of emissions in project fuel use.
		N_2O	No	Not a significant source of emissions in project fuel use.

6 BASELINE SCENARIO

6.1 Determination of the Most Plausible Baseline Scenario

At the project start date, the most plausible baseline scenario for tidal wetland restoration projects must be identified as degraded tidal wetlands, or mudflats or shallow open water, in which establishment of wetland ecological conditions is not expected to occur in the absence of the project activity.

For projects not eligible to apply the activity method for demonstrating additionality (see Section 7.1 below), the baseline scenario must be determined using the latest version of CDM tool *Combined tool to identify the baseline scenario and demonstrate additionality for A/R CDM project activities*. This tool has been designed for CDM A/R project activities, and is used in this methodology noting the following:

Where the tool refers to:	It must be understood as referring to:
A/R, afforestation, reforestation, or forestation	WRC or WRC/ARR, or restoration
Net greenhouse gas removals by sinks	Net greenhouse gas emission reductions
CDM	VCS
DOE	VVB
tCERs, lCERs	VCUs

Step 0 and sub-step 2b, paragraph 15 (regarding forested areas since 31 December 1989), must be disregarded. Footnotes 1-3 may also be disregarded[5].

For projects eligible to apply the activity method for demonstrating additionality (see Section 7.1 below), all elements of the tool related to additionality must be disregarded.

6.2 Reassessment of the Baseline Scenario

The project proponent must reassess the baseline scenario in accordance with the VCS rules.

For this reassessment, when applying the *Fire Reduction Premium* approach specified in Section 8.3, the historic reference period must be extended to include the original reference period and all subsequent monitoring periods up to the beginning of the current monitoring period. The fire reference period must not be extended, as this is a fixed 10-year period ending 5 years before the

[5] Sub-step and footnotes as in version 01 of the tool, the prevailing version of the tool as of the writing of this methodology.

project start date.

In addition, the project proponent must, for the duration of the project, re-determine, where applicable, the PDT every 10 years. This reassessment must use the procedure specified in Section 5.1. Data sources must be updated where new information relevant to the project area has become available.

7 ADDITIONALITY

7.1 Projects Located in the United States

This methodology uses an activity method for the demonstration of additionality of tidal wetland restoration projects located in the United States.

Step 1: Regulatory surplus

The project proponent must demonstrate regulatory surplus in accordance with the rules and requirements regarding regulatory surplus set out in the latest version of the *VCS Standard*.

Step 2: Positive list

The applicability conditions of this methodology represent the positive list. The positive list was established using the activity penetration option (Option A in the *VCS Standard*). Projects located in the United States[6], and which meet all of the applicability conditions of this methodology, are deemed additional.

Justification for the activity method is provided in Appendix 2.

7.2 Projects Located outside the United States

This methodology uses a project method for tidal wetland restoration projects located outside the United States. Such projects must use the latest version of the CDM *Combined tool to identify the baseline scenario and demonstrate additionality for A/R CDM project activities* for the demonstration of additionality, taking into account the additional guidance provided in Section 6.1 above.

[6] Defined as the 35 coastal states, commonwealths or territories of the United States of America.

8 QUANTIFICATION OF GHG EMISSION REDUCTIONS AND REMOVALS

8.1 Baseline Emissions

8.1.1 General approach

Emissions in the baseline scenario are attributed to carbon stock changes in biomass carbon pools, soil processes, or a combination of these. In addition, where relevant, emissions from fossil fuel use may be quantified.

Emissions in the baseline scenario are estimated as:

$$GHG_{BSL} = GHG_{BSL\text{-}biomass} + GHG_{BSL\text{-}soil} + GHG_{BSL\text{-}fuel} \quad \textbf{(17)}$$

$$GHG_{BSL-biomass} = -\sum_{t=1}^{t^*} \sum_{i=1}^{M_{BSL}} \left(\frac{44}{12} \times \Delta C_{BSL-biomass,i,t} \right) \quad \textbf{(18)}$$

$$GHG_{BSL-soil} = \sum_{t=1}^{t^*} \sum_{i=1}^{M_{BSL}} GHG_{BSL-soil,i,t} \quad \textbf{(19)}$$

$$GHG_{BSL-fuel} = \sum_{t=1}^{t^*} \sum_{i=1}^{M_{BSL}} GHG_{BSL-fuel,i,t} \quad \textbf{(20)}$$

Where:

GHG_{BSL}	Net CO_2e emissions in the baseline scenario up to year t^*; t CO_2e
$GHG_{BSL\text{-}biomass}$	Net CO_2e emissions from biomass carbon pools in the baseline scenario up to year t^*; t CO_2e
$GHG_{BSL\text{-}soil}$	Net CO_2e emissions from the SOC pool in the baseline scenario up to year t^*; t CO_2e
$GHG_{BSL\text{-}fuel}$	Net CO_2e emissions from fossil fuel use in the baseline scenario up to year t^*; t CO_2e
$\Delta C_{BSL\text{-}biomass,i,t}$	Net carbon stock changes in biomass carbon pools in the baseline scenario in stratum i in year t; t C yr^{-1}
$GHG_{BSL\text{-}soil,i,t}$	GHG emissions from the SOC pool in the baseline scenario in stratum i in year t; t CO_2e yr^{-1}
$GHG_{BSL\text{-}fuel,i,t}$	GHG emissions from fossil fuel use the baseline scenario in stratum i in year t; t CO_2e yr^{-1}
i	1, 2, 3 …M_{BSL} strata in the baseline scenario
t	1, 2, 3, … t^* years elapsed since the project start date

Estimation of GHG emissions and removals related to the biomass pool is based on carbon stock changes. Estimation of GHG emissions and removals from the SOC pool is based on either various proxies (eg, carbon stock change, water table depth) or through the use of literature, data, default factors or models.

Assessing GHG emissions in the baseline scenario consists of determining GHG emission proxies/parameters and assessing their pre-project spatial distribution, constructing a time series of the chosen proxies/parameters for each stratum for the entire project crediting period and determining annual GHG emissions per stratum for the entire project crediting period.

In order to project the future GHG emissions from soil per unit area in each stratum for each projected verification date within the project crediting period under the baseline scenario, the project proponent must apply the latest version of VCS module *VMD0019 Methods to Project Future Conditions*. When applying Steps 13 and 14 of *VMD0019* (version 1, issued 16 November 2012, the version of the module current as of the writing of this methodology) the project proponent must use the guidance for sea level rise provided in Section 5.2 of this methodology.

Four driving factors are likely to be relevant for GHG accounting in the baseline scenario, and are relevant for use of *VMD0019*. Each factor affects the evolution of the site over a 100-year period. These include:

- Initial land use and development patterns.
- Initial infrastructure that impedes natural tidal hydrology.
- Natural plant succession for the physiographic region of the project.
- Climate variables as likely drivers of changes in tidal hydrology within the 100-year timeframe of the project, influencing sea level rise, precipitation and associated freshwater delivery.

Land use and development patterns – In order to derive trends in land use, assumptions about the likelihood of future development of the project area must be documented and considered in light of current zoning, regulatory constraints to development, proximity to urban areas or transportation infrastructure, and expected population growth, including how land would develop within and surrounding the project site and how such changes would change hydrologic conditions within the project area. Current development patterns and plausible future land use changes must be mapped to a scale sufficient to estimate GHG emissions from the baseline scenario. In the case of abandonment of pre-project land use in the baseline scenario, the project proponent must consider non-human induced hydrologic changes brought about by collapsing dikes or ditches that would have naturally closed over time, and progressive subsidence, leading to rising relative water levels, increasingly thinner aerobic layers and reduced CO_2 emission rates.

Infrastructure impediments to tidal hydrology – In order to derive trends in tidal wetland evolution, the baseline scenario must take into account the current and historic layout of any tidal barriers and drainage systems. The tidal barriers and drainage layout at the start of the project activity must be mapped at scale (1:10,000 or any other scale justified for estimating water table depths throughout the project area). Historic tidal barriers and drainage layout must be mapped using topographic and/or hydrological maps from (if available) the start of the major hydrological impacts but covering at least the 20 years prior to the project start date. Historic drainage structures (collapsed ditches) may (still) have higher hydraulic conductivity than the surrounding areas and function as preferential flow paths. Historic tidal barriers (agricultural dikes and levees) may constrain the tidal flows and prevent natural sedimentation patterns. The effect of historic tidal barriers and drainage structures on current hydrological functioning of the project area must be assessed on the basis of quantitative hydrological modeling and/or expert judgment.

Historic information on the pre-existing channel network as determined by aerial photography may serve to set trends in post-project dendritic channel formation in the field. Derivation of such trends must be performed on the basis of hydrologic modeling using the total tidal volume, soil erodibility and/or expert judgment. With respect to hydrological functioning, the baseline scenario must be restricted by climate variables and quantify any impacts on the hydrological functioning as caused by planned measures outside the project area (eg, dam construction or further changes in hydrology such as culverts), by demonstrating a hydrological connection to the planned measures.

Natural plant succession - Based on the assessment of changes in water table depth, a time series of vegetation composition must be derived *ex ante*, based on vegetation succession schemes in the baseline scenario from scientific literature or expert judgment. For example, diked agricultural land will undergo natural plant succession to forests, freshwater wetlands, tidal wetlands, rank uplands, or open water based on the scenario's land use trajectory, inundation scenario, proximity to native or invasive seed sources, plant succession trajectories of adjacent natural areas or likely maintenance consistent with projected future human land use (eg, pasture, lawn, landscaping).

Climate variables – Consistent with the sea level rise guidance provided in Section 5.2 above, areas of inundation and erosion within the project area must be considered in relation to the above three factors. Expected changes in freshwater delivery associated with changes in rainfall patterns must be considered, including expected human responses to these changes.

The project proponent must, for the duration of the project crediting period, reassess the baseline scenario every 10 years. Based on the reassessment criteria specified in Section 6 above, the revised baseline scenario must be incorporated into revised estimates of baseline emissions. This baseline reassessment must include the evaluation of the validity of proxies for GHG emissions.

8.1.2 Accounting for sea level rise

The consequences of submergence of a given stratum due to sea level rise are:

1) Carbon stocks from aboveground biomass are lost to oxidation, and

2) Depending upon the geomorphic setting, soil carbon stocks may be held intact or be eroded and transported beyond the project area.

Regarding (1) above, where biomass is submerged, it is assumed that this carbon is immediately and entirely returned to the atmosphere. For such strata:

$$\Delta C_{BSL\text{-}biomass,i,t} = 12/44 \times (C_{BSL\text{-}biomass,i,t} - C_{BSL\text{-}biomass,i,(t\text{-}T)}) / T \qquad \textbf{(21)}$$

For the year of submergence:

$$C_{BSL\text{-}biomass,i,t} = 0$$

Where:

$\Delta C_{BSL\text{-}biomass,i,t}$	Net carbon stock change in biomass carbon pools in the baseline scenario in stratum *i* in year *t*; t C yr^{-1}
$C_{BSL\text{-}biomass,i,t}$	Carbon stock in biomass in the baseline scenario in stratum *i* in year *t* (from $C_{TREE\_BSL,t}$ in *AR-Tool14*); t CO_2e
i	1, 2, 3 …M_{WPS} strata in the baseline scenario
t	1, 2, 3, … *t** years elapsed since the project start date
T	Time elapsed between two successive estimations (T=$t_2 - t_1$)

The gradual loss of vegetation in the project area due to submergence may be captured by detailed stratification into areas with and without vegetation.

For strata where conversion to open water is expected before *t* = 100, the long-term average of $C_{TREE\_BSL,t}$ and $C_{SHRUB\_BSL,t}$ in *AR-Tool14* must be calculated as defined in Section 8.2.3.

Regarding (2) above, the project proponent may apply models (see Section 8.1.4.2) to assess the time and rate of submergence of the project area.

For areas that drown out while the area of ponds increases, the loss of SOC may be assumed to be insignificant. It is assumed that, upon submergence, soil carbon is not returned to the atmosphere unless site-specific scientific justification is provided.

In areas with wave action, sediment will erode and carbon will be removed. Assuming that all carbon is re-sedimented and stored (and not oxidized) is conservative. The project proponent may justify a greater oxidation rate for the baseline scenario based on appropriate scientific research.

Restoration projects may be designed in such a way that they have advantages over the baseline scenario in one or more of the following ways, as must be quantified and justified in the project description:

- The point in time when submergence and erosion sets off.

- The amount of carbon that erodes upon submergence.
- The oxidation rate of eroded soil organic matter. In the most conservative approach, the oxidation constant is 0 for the baseline and 1 for the project scenario.

8.1.3 Net carbon stock change in biomass carbon pools in baseline scenario

Net carbon stock change in biomass carbon pools in the baseline scenario are estimated as:

$$\Delta C_{BSL\text{-}biomass,i,t} = \Delta C_{BSL\text{-}tree/shrub,i,t} + \Delta C_{BSL\text{-}herb,i,t} \quad \textbf{(22)}$$

Where:

$\Delta C_{BSL\text{-}biomass,i,t}$	Net carbon stock change in biomass carbon pools in the baseline scenario in stratum *i* in year *t*; t C yr^{-1}
$\Delta C_{BSL\text{-}tree/shrub,i,t}$	Net carbon stock change in tree and shrub carbon pools in the baseline scenario in stratum *i* in year *t*; t C yr^{-1}
$\Delta C_{BSL\text{-}herb,i,t}$	Net carbon stock change in herb carbon pools in the baseline scenario in stratum *i* in year *t*; t C yr^{-1}
i	1, 2, 3 …M_{BSL} strata in the baseline scenario
t	1, 2, 3, … *t** years elapsed since the project start date

Trees and shrubs

Net carbon stock change in trees and shrubs in the baseline scenario are estimated by applying the latest version of CDM tool *AR-Tool14 Estimation of carbon stocks and change in carbon stocks of trees and shrubs in A/R CDM project activities*, noting that:

1) *AR-Tool14* is only used to derive net carbon stock changes in tree and shrub carbon pools ($\Delta C_{BSL\text{-}tree/shrub,i,t}$), and
2) The following equation applies:

$$\Delta C_{BSL\text{-}tree/shrub,i,t} = 12/44 \times (\Delta C_{TREE\_BSL,t} + \Delta C_{SHRUB\_BSL,t}) \quad \textbf{(23)}$$

Where:

$\Delta C_{BSL\text{-}tree/shrub,i,t}$	Net carbon stock changes in tree and shrub carbon pools in the baseline scenario in stratum *i* in year *t*; t C yr^{-1}
$\Delta C_{TREE\_BSL,t}$	Change in carbon stock in baseline tree biomass within the project area in year *t*; t CO_2-e yr^{-1} (derived from application of *AR-Tool14*; calculations are done for each stratum *i*)
$\Delta C_{SHRUB\_BSL,t}$	Change in carbon stock in baseline shrub biomass within the project area in year *t*; t CO_2-e yr^{-1} (derived from application of *AR-Tool14*; calculations are done for each stratum *i*)

For strata where reforestation or revegetation activities in the baseline scenario include harvesting, the long-term average of $C_{TREE\_BSL,t}$ in *AR-Tool14* must be calculated as specified in Section 8.2.3.

Herbaceous vegetation

Net carbon stock change in herbaceous vegetation in the baseline scenario is estimated using a carbon stock change approach as follows:

$$\Delta C_{BSL\text{-}herb,i,t} = (C_{BSL\text{-}herb,i,t} - C_{BSL\text{-}herb,i,,(t-T)}) / T \quad \textbf{(24)}$$

Where:

$\Delta C_{BSL\text{-}herb,i,t}$	Net carbon stock change in herbaceous vegetation carbon pools in the baseline scenario in stratum *i* in year *t*; t C yr^{-1}
$C_{BSL\text{-}herb,i,t}$	Carbon stock in herbaceous vegetation in the baseline scenario in stratum *i* in year *t*; t C
i	1, 2, 3 …M_{BSL} strata in the baseline scenario
t	1, 2, 3 … *t** years elapsed since the project start date
T	Time elapsed between two successive estimations ($T=t_2 - t_1$)

A default factor7 for carbon stock in herbaceous vegetation of 3 t C ha^{-1} may be applied for strata with 100 percent herbaceous cover. For areas with a vegetation cover <100 percent, a 1:1 relationship between vegetation cover and carbon stock must be applied. The default factor may be claimed only for the first year of the project crediting period as herbaceous biomass quickly reaches a steady state. Vegetation cover must be determined by commonly used techniques in field biology. Procedures for measuring carbon stocks in herbaceous vegetation are provided in Section 9.3.6. The above default factor may not be applied in case *AR-Tool14* is used.

Where a carbon stock increase in herbaceous vegetation is quantified in the project scenario, carbon stock changes must also be quantified in the baseline scenario; where a carbon stock decline is quantified in the baseline scenario, carbon stock changes must also be quantified in the project scenario.

---

[7] Calculated from peak aboveground biomass data from 20 sites summarized in Mitsch & Gosselink. The median of these studies is 1.3 kg d.m. m^{-2}. This was converted to the default factor value as follows: 1.3 × 0.45 × 0.5. The factor 0.45 converts organic matter mass to carbon mass; the factor 0.5 is a factor that averages annual peak biomass (factor = 1) and annual minimum biomass (factor = 0, assuming ephemeral aboveground biomass and complete litter decomposition).

8.1.4 Net GHG emissions from soil in baseline scenario

8.1.4.1 General

Net GHG emissions from soil in the baseline scenario are estimated as:

$$GHG_{BSL\text{-}soil,i,t} = A_{i,t} \times (GHG_{BSL\text{-}soil\text{-}CO2,i,t} - Deduction_{alloch} + GHG_{BSL\text{-}soil\text{-}CH4,i,t} + GHG_{BSL\text{-}soil\text{-}N2O,i,t}) \quad \textbf{(25)}$$

For organic soils where $t > t_{PDT\text{-}BSL,i}$:

$GHG_{BSL\text{-}soil,i,t} = 0$

For mineral soils where $t > t_{SDT\text{-}BSL,i}$:

$GHG_{BSL\text{-}soil,i,t} = 0$

Where:

$GHG_{BSL\text{-}soil,i,t}$	GHG emissions from the SOC pool in the baseline scenario in stratum i in year t; t CO_2e yr^{-1}
$GHG_{BSL\text{-}soil\text{-}CO2,i,t}$	CO_2 emissions from the SOC pool in the baseline scenario in stratum i in year t; t CO_2e ha^{-1} yr^{-1}
$Deduction_{alloch}$	Deduction from CO_2 emissions from the SOC pool to account for the percentage of the carbon stock that is derived from allochthonous soil organic carbon; t CO_2e ha^{-1} yr^{-1}
$GHG_{BSL\text{-}soil\text{-}CH4,i,t}$	CH_4 emissions from the SOC pool in the baseline scenario in stratum i in year t; t CO_2e ha^{-1} yr^{-1}
$GHG_{BSL\text{-}soil\text{-}N2O,i,t}$	N_2O emissions from the SOC pool in the baseline scenario in stratum i in year t; t CO_2e ha^{-1} yr^{-1}
$A_{i,t}$	Area of stratum i in year t; ha
$t_{PDT\text{-}BSL,i}$	Peat depletion time in the baseline scenario in stratum i in years elapsed since the project start date; yr
$t_{SDT\text{-}BSL,i}$	Soil organic carbon depletion time in the baseline scenario in stratum i in years elapsed since the project start date; yr
i	1, 2, 3 …M_{BSL} strata in the baseline scenario
t	1, 2, 3, … t^* years elapsed since the project start date

GHG emissions from disturbed carbon stocks in stockpiles (originating from piling, dredging, channelization) exposed to aerobic decomposition must be accounted for in the baseline scenario. Such stockpiles must be identified in the stratification of the project area and accounting procedures provided in this Section 8.1.4 must be used.

The baseline scenario may involve the construction of levees to constrain flow and flooding patterns, the construction of dams to hold water, and/or upstream changes in land surface leading to intensified run-off. In such cases, the project proponent must account for hydrological processes that lead to increased carbon burial and GHG reductions within the project area using procedures provided in this section.

The sub-sections below provide guidance with respect to the methods which may be used to estimate net GHG emissions from soil in the baseline scenario.

Use of proxies

Proxies (as defined in VCS document *Program Definitions*) may be used to derive values of GHG emissions. The project proponent must demonstrate that such proxies are strongly correlated with the value of interest and that they can serve as an equivalent or better method (eg, in terms of reliability, consistency or practicality) to determine the value of interest than direct measurement of the value itself. Such proxies must also have been developed and tested for use in systems that are in the same or similar region as the project area, share similar geomorphic, hydrologic, and biological properties, and are under similar management regimes, unless any differences should not have a substantial effect on GHG emissions.

Use of models

The project proponent may apply deterministic models (models as defined in VCS document *Program Definitions*) to derive values of GHG emissions. In addition to the VCS requirements for selection and use of models, modeled GHG emissions and removals must have been validated with direct measurements from a system with the same or similar water table depth and dynamics, salinity, tidal hydrology, sediment supply and plant community type as the project area.

Use of published data

Peer-reviewed published data may be used to generate values for the average rate of GHG emissions in the same or similar systems as those in the project area. Such data must be limited to systems that are in the same or similar region as the project area, share similar geomorphic, hydrologic, and biological properties, and are under similar management regimes unless any differences should not have a substantial effect on GHG emissions.

Use of default factors

Emission factors must be derived from peer-reviewed literature and must be appropriate to ecosystem type and conditions and the geographic region of the project area.

The default factors in Sections 8.1.4.2.3, 8.1.4.4.4, and 8.1.4.5.4 are subject to periodic re-assessment per the requirements for periodic assessment of default factors set out in VCS document *Methodology Approval Process*.

IPCC default factors[8] may be used as indicated in this methodology. Tier 1 values may be used, but their use must be justified as appropriate for project conditions.

8.1.4.2 CO_2 emissions from soil

CO_2 emissions from soils may be estimated using:

1) Proxies;
2) Published values;
3) Default factors;
4) Models;
5) Field-collected data; or
6) Historical or chronosequence-derived data.

In certain cases allochthonous soil organic carbon may accumulate in the project area. Procedures for the estimation of a compensation factor for allochthonous soil organic carbon are specified in Section 8.1.4.3.

8.1.4.2.1 Proxy-based approach

CO_2 emissions may be estimated using proxies such as water table depth, soil subsidence and carbon stock change (where such proxies meet the guidance set out in Section 8.1.4.1 above). Where the project proponent uses a proxy, such emissions are represented by the following equation:

$$GHG_{BSL\text{-}soil\text{-}CO2,i,t} = f\ (\text{GHG emission proxy}) \qquad \textbf{(26)}$$

<u>Water table depth</u>

Water table depth may be used as a proxy for CO_2 emissions for mineral and organic soils where the project proponent is able to justify their use as described in Section 8.1.4.1.

When using water table depth as a proxy, it must be projected for the 10-year baseline period through hydrologic modeling, taking into consideration the following:

- Long-term average climate variables (over 20+ years prior to the project start date from two climate stations nearest to the project area) influencing water levels and the timing and quantity of water flow;
- Planned water management activities documented in existing land management plans, predating consideration of the proposed project activity; and

---

[8] 2013 Supplement to the 2006 Guidelines: Wetlands

- Potential offsite influences (eg, changes in sedimentation rates, upstream water supply, sea level rise).

If the mean annual water table depth in the project area exceeds the depth range for which the emission-water table depth relationship determined for the project is valid, a conservative extrapolation must be used.

Subsidence

Soil subsidence may also be used as a proxy for CO_2 emissions from the SOC pool, using the equation below:

$$GHG_{BSL\text{-}soil\text{-}CO2,i,t} = 44/12 \times C_{peatloss\text{-}BSL,i,t} \quad \textbf{(27)}$$

$$C_{peatloss\text{-}BSL,i,t} = 10 \times Rate_{subs\text{-}BSL,i} \times VC \quad \textbf{(28)}$$

Where:

$GHG_{BSL\text{-}soil\text{-}CO2,i,t}$	CO_2 emissions from the SOC pool in the baseline scenario in stratum *i* in year *t*; t CO_2e ha^{-1} yr^{-1}
$C_{peatloss\text{-}BSL,i,t}$	Organic soil carbon loss due to subsidence in the baseline scenario in subsidence stratum *i* in year *t*; t C ha^{-1}
$Rate_{subs\text{-}BSL,i}$	Rate of organic soil loss due to subsidence in the baseline scenario in stratum *i*; m yr^{-1}
VC	Volumetric organic carbon content of organic soil; kg C m^{-3}
i	1, 2, 3 …M_{BSL} subsidence strata in the baseline scenario
t	1, 2, 3 … *t** years elapsed since the start of the project activity

Carbon stock change

Carbon stock change may also be used as a proxy for CO_2 emissions from the SOC pool, using the equation below:

$$GHG_{BSL\text{-}soil\text{-}CO2,i,t} = 44/12 \times -(C_{BSL\text{-}soil,i,t} - C_{BSL\text{-}soil,i,,(t-T)}) / T \quad \textbf{(29)}$$

Where:

$GHG_{BSL\text{-}soil\text{-}CO2,i,t}$	CO_2 emissions from the SOC pool in the baseline scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
$C_{BSL\text{-}soil,i,t}$	Soil organic carbon stock in the baseline scenario in stratum *i* in year *t*; t C ha^{-1}
i	1, 2, 3 …M_{BSL} strata in the baseline scenario
t	1, 2, 3 … *t** years elapsed since the start of the project activity
T	Time elapsed between two successive estimations ($T=t_2 - t_1$)

8.1.4.2.2 Published values

Peer-reviewed published data may be used to generate a value for $GHG_{BSL\text{-}soil\text{-}CO2,i,t}$ based on the average rate of CO_2 emissions in the same or similar systems as those in the project area, based on the guidelines set out in Section 8.1.4.1 above. Refer also to the instructions in Section 5.1 above for the estimation of the rate of organic soil carbon loss due to oxidation in the baseline scenario from mineral soils ($Rate_{Closs\text{-}BSL}$).

8.1.4.2.3 Default factors

For tidal marsh and mangrove systems, a default factor may be used in the absence of data suitable for using the published value approach, using the value provided below:

$$GHG_{BSL\text{-}soil\text{-}CO2,i,t} = -1.46^{(9)}\ t\ C\ ha^{-1}\ yr^{-1} \times 44/12 \quad \textbf{(30)}$$

The above default factor may only be applied to areas with a crown cover of at least 50 percent. By contrast, for areas with a crown cover of less than 15 percent, this value may be assumed to be insignificant and accounted for as zero.

In the absence of data suitable for using the published value approach, the most recently published IPCC emission factors[10] may be used to estimate CO_2 emissions from the SOC pool, except for tidal marsh and mangrove systems.

8.1.4.2.4 Modeling

A peer-reviewed published model may be used to generate a value of $GHG_{BSL\text{-}soil\text{-}CO2,i,t}$ in the same or similar systems as those in the project area based on the guidelines set out in Section 8.1.4.1 above.

8.1.4.2.5 Field-collected data

Soil coring may be used to generate a value of $C_{BSL\text{-}soil,i,t}$ as outlined in Section 9.3.7. For the baseline scenario, soil cores must be collected within 2 years prior to the project start date. Where the project proponent uses an installed reference plane for the baseline scenario, it must have been installed at least 4 years prior to the baseline measurement, which is good practice to ensure that a reliable average accumulation rate is obtained.

8.1.4.2.6 Historical data or chronosequences

The rate of organic soil carbon loss due to oxidation in the baseline scenario from mineral soils

---

[9] (within equation 30) This default factor was derived from the median rate of the literature synthesis of Chmura et al. 2003. The synthesis included studies worldwide, including marshes and mangroves. The median was used as the best estimate of central tendency because the data were not normally distributed.

[10] 2013 Supplement to the 2006 Guidelines: Wetlands

($Rate_{Closs\text{-}BSL}$) may be estimated using either historical data collected from the project area (as described in Section 9.3.7) or chronosequence data collected at similar sites (as described in Section 8.1.4.1). Refer also to the instructions set out in Section 5.1. CO_2 emissions from the SOC pool are calculated as follows:

$$GHG_{BSL\text{-}soil\text{-}CO2,i,t} = Rate_{Closs\text{-}BSL,i,t} \times 44/12 \quad \textbf{(31)}$$

Where:

$GHG_{BSL\text{-}soil\text{-}CO2,i,t}$	CO_2 emissions from the SOC pool in the baseline scenario in stratum *i* in year *t*; t CO_2e ha^{-1} yr^{-1}
$Rate_{Closs\text{-}BSL,i,t}$	Rate of organic carbon loss in mineral soil due to oxidation in the baseline scenario in stratum *i* in year *t*; t C ha^{-1} yr^{-1}.
i	1, 2, 3 …M_{BSL} strata in the baseline scenario
t	1, 2, 3 … *t** years elapsed since the start of the project activity

8.1.4.3 Deduction for allochthonous carbon

A deduction from the estimate of CO_2 emissions from the SOC pool must be applied to account for the percentage of sequestration resulting from allochthonous soil organic carbon accumulation. A deduction must not be used if the approach used above to estimate CO_2 emissions directly estimates autochthonous CO_2 emissions or otherwise accounts for allochthonous carbon.

$$Deduction_{alloch} = GHG_{BSL\text{-}soil\text{-}CO2,i,t} \times (\%C_{alloch} /100) \quad \textbf{(32)}$$ [11]

Where:

$Deduction_{alloch}$	Deduction from CO_2 sequestration in the SOC pool to account for the percentage of the carbon stock that is derived from allochthonous soil organic carbon; t CO_2e ha^{-1} yr^{-1}
$GHG_{BSL\text{-}soil\text{-}CO2,i,t}$	CO_2 emissions from the SOC pool in the baseline scenario in stratum *i* in year *t*; t CO_2e ha^{-1} yr^{-1}
$\%C_{alloch}$	Percentage of the total soil organic carbon that is allochthonous; %
i	1, 2, 3 …M_{BSL} strata in the baseline scenario
t	1, 2, 3 … *t** years elapsed since the start of the project activity

$Deduction_{alloch}$ may be conservatively set to zero in the baseline scenario.

For strata with organic soils or seagrass systems[12], $Deduction_{alloch}$ = 0.

---

[11] Estimation may be made for total or recalcitrant allochthonous carbon. This equation only applies if $GHG_{BSL\text{-}soil\text{-}CO2,i,t}$ is negative (sequestration).

$\%C_{alloch}$ may be estimated using either:

1) Published values
2) Field-collected data
3) Modeling

Published values

Peer-reviewed published data may be used to generate a value of the percentage of allochthonous soil organic carbon in the same or similar systems as those in the project area based on the guidelines described in Section 8.1.4.1.

Field-collected data

For this method, the allochthonous carbon percentage is estimated using default values (listed below) and measured through analysis of field-collected soil cores (for soil carbon or organic matter), sediment tiles (for deposited sediment carbon or organic matter), or through collection of suspended sediments in tidal channels or sediments deposits in tidal flats (for sediment carbon or organic matter).

For the following equation, $\%C_{soil}$ may be measured directly or derived from $\%OM_{soil}$ using the equations in Section 9.3.7. $\%C_{autoch}$ is derived from $\%OM_{autoch}$ (defined below) using the equations in Section 9.3.7.

$$\%C_{alloch} = 100 \times (\%C_{soil} - \%C_{autoch}) / \%C_{soil} \quad \textbf{(33)}$$

Where:

$\%C_{alloch}$	Percentage of the total soil organic carbon that is allochthonous; %
$\%C_{soil}$	Percentage of soil that is organic carbon; %
$\%C_{autoch}$	Percentage of soil that is autochthonous organic carbon; %

For the following equation, $\%OM_{soil}$ may be estimated directly using loss-on-ignition (LOI) data or indirectly from $\%C_{soil}$ using the equations below. $\%OM_{depsed}$ may be estimated directly using loss-on-ignition (LOI) data, indirectly from $\%OM_{soil}$ using the equations below, or by using the default value given below.

$$\%OM_{autoch} = (\%OM_{soil} - \%OM_{depsed}) / (1 - (\%OM_{depsed} / 100)) \quad \textbf{(34)}$$

[12] For seagrass systems, this zero deduction may only be used when the 'layer with soil organic carbon indistinguishable from the baseline SOC concentration' method is used with field-collected data on carbon stock changes (Duarte 2013, Greinier *et al*. 2013)

Where:

$\%OM_{autoch}$	Percentage of soil that is autochthonous organic matter; %
$\%OM_{depsed}$	Percentage of deposited sediment that is organic matter; %
$\%OM_{soil}$	Percentage of soil that is soil organic matter; %

The following equations may be used to derive $\%OM_{soil}$ from $\%C_{soil}$ and $\%OM_{depsed}$ from $\%C_{depsed}$, respectively. Alternatively, an equation developed using site-specific data may be used or an equation from peer-reviewed literature may be used if the equation represents soils from the same or similar systems as those in the project area.

For marsh soils[13]*:*

$$\%OM_{soil} = (-0.4 + \sqrt{(0.4^2 + 4 \times 0.0025 \times \%C_{soil}}) \Big/ (2 \times 0.0025) \quad \textbf{(35)}$$

$$\%OM_{depsed} = (-0.4 + \sqrt{(0.4^2 + 4 \times 0.0025 \times \%C_{depsed}})) \Big/ (2 \times 0.0025) \quad \textbf{(36)}$$

For mangrove soils[14]:

$$\%OM_{soil} = \%C_{soil} \times 1.724 \quad \textbf{(37)}$$

$$\%OM_{depsed} = \%C_{depsed} \times 1.724 \quad \textbf{(38)}$$

For seagrass soils with $\%OM$ < 20 percent[15]*:*

$$\%OM_{soil} = (\%C_{soil} + 0.21) / 0.4 \quad \textbf{(39)}$$

$$\%OM_{depsed} = (\%C_{depsed} + 0.21) / 0.4 \quad \textbf{(40)}$$

Where:

$\%C_{soil}$	Percentage of soil that is organic carbon; %
$\%C_{depsed}$	Percentage of deposited sediment that is organic C; %

In all cases, the following default factor may be used for the determination of $\%OM_{depsed}$:

$\%OM_{depsed}$ = 3.0[16]

---

[13] Craft *et al.* 1991

[14] Allen 1974

[15] Fourqurean *et al*. 2012 as summarized in Howard *et al.* 2014

[16] Andrews *et al.* 2011

Modeling

A quantitative model may be used to estimate the percent of allochthonous soil organic carbon where such model meets the guidelines set out in Section 8.1.4.1 above. The modeled percentage allochthonous soil organic carbon must be verified with direct measurements from a system with similar water table depth and dynamics, salinity and plant community type as the project area. The model must be accepted by the scientific community as shown by publication in a peer-reviewed journal and repeated application to different wetland systems.

8.1.4.4 CH_4 emissions from soil

CH_4 emissions from soil in the baseline scenario may be conservatively excluded.

CH_4 emissions from soils may be estimated using:

1) Proxies;
2) Field-collected data
3) Published values;
4) Default factors;
5) Models; or
6) IPCC emission factors.

Where the project proponent accounts for CH_4 emissions in the baseline scenario, the options described in the sections below may be applied to estimate such emissions.

8.1.4.4.1 Proxy-based approach

Where relevant, CH_4 emissions from organic soil may be estimated using proxies such as water table depth and vegetation composition (where such proxies meet the requirements set out in Section 8.1.4.1 above). Where the project proponent uses a proxy, such emissions are represented by the following equation:

$$GHG_{BSL\text{-}soil\text{-}CH4,i,t} = f\,(\text{GHG emission proxy}) \times CH_4\text{-}GWP \qquad \textbf{(41)}$$

Where:

$GHG_{BSL\text{-}soil\text{-}CH4,i,t}$	CH_4 emissions from the SOC pool in the baseline scenario; t CO_2e ha^{-1} yr^{-1}
f (GHG emission proxy)	Proxy for CH_4 emissions; t CH_4 ha^{-1} yr^{-1}
$CH_4\text{-}GWP$	Global warming potential of CH_4; dimensionless

8.1.4.4.2 Field-collected data

Field-collected data may also be used to estimate CH_4 emissions (see Section 9.3.8).

8.1.4.4.3 Published values

Peer-reviewed published data may be used to generate a value based on the average CH_4 emissions rate in the same or similar systems as those in the project area based on the guidelines set out in Section 8.1.4.1 above.

8.1.4.4.4 Default factor

For tidal wetland systems, a default factor[17] may be used in the absence of data suitable for using the published value *approach* for the estimation of $GHG_{BSL\text{-}soil\text{-}CH4,i,t}$. Where the salinity average or salinity low point is >18 ppt, the project proponent may apply a default emission factor of:

$$GHG_{BSL\text{-}soil\text{-}CH4,i,t} = 0.011 \text{ t } CH_4 \text{ ha}^{-1} \text{ yr}^{-1} \times CH_4\text{-}GWP \quad \textbf{(42)}$$

Where the salinity average or salinity low point is ≥ 20 ppt, the project proponent may apply a default emission factor of:

$$GHG_{BSL\text{-}soil\text{-}CH4,i,t} = 0.0056 \text{ t } CH_4 \text{ ha}^{-1} \text{ yr}^{-1} \times CH_4\text{-}GWP \quad \textbf{(43)}$$

Procedures for measuring the salinity average or salinity low point are provided in Section 9.3.8.

The project proponent must not use the default value of 0.011 t CH_4 ha^{-1} yr^{-1} for the baseline scenario and 0.0056 t CH_4 ha^{-1} yr^{-1} for the project scenario to create a difference in emissions and claim an emission reduction. The use of the default factor is intended for projects that restore salinity levels from fresh/brackish to much higher levels that inhibit CH_4 emissions.

8.1.4.4.5 Modeling

A quantitative model which meets the guidance set out in Section 8.1.4.1 above may also be used to estimate CH_4 emissions from the SOC pool.

8.1.4.4.6 Emission factors

The most recently published IPCC emission factors may be used to estimate CH_4 emissions from the SOC pool for non-tidal wetland systems. Tier 1 values may also be used, but must be applied conservatively including accounting for local salinity and vegetative cover conditions.

8.1.4.5 N_2O emissions from soil

N_2O emissions may be conservatively excluded in the baseline scenario.

---

[17] Taken from Poffenbarger *et al.* 2011

N_2O emissions from soils may be estimated using:

1) Proxies;
2) Field-collected data;
3) Published values;
4) Default factors;
5) Models; or
6) IPCC emission factors.

Where the project proponent accounts for N_2O emissions in the baseline scenario, the options described in the sections below may be applied to estimate such emissions.

8.1.4.5.1 Proxy-based approach

Where relevant, N_2O emissions may be estimated using proxies such as water table depth and vegetation composition (where such proxies meet the guidance set out in Section 8.1.4.1 above). Where the project proponent uses a proxy, such emissions are represented by the following equation (note that the determination of the similarity of systems must include the nitrogen levels of the systems):

$$GHG_{BSL\text{-}soil\text{-}N2O,i,t} = f\ (N_2O \text{ emission proxy}) \times N_2O\text{-}GWP \quad \textbf{(44)}$$

Where:

$GHG_{BSL\text{-}soil\text{-}N2O,i,t}$	N_2O emissions from the SOC pool in the baseline scenario due to denitrification/nitrification; t CO_2e ha^{-1} yr^{-1}
f (N_2O emission proxy)	Proxy for N_2O emissions; t N_2O ha^{-1} yr^{-1}
$N_2O\text{-}GWP$	Global warming potential for N_2O; dimensionless

8.1.4.5.2 Field-collected data

Field-collected data may be used to estimate N_2O emissions (see Section 9.3.8).

8.1.4.5.3 Published values

Peer-reviewed published data may be used to generate a value based on the average N_2O emissions rate in the same or similar systems as those in the project area based on the guidelines described in Section 8.1.4.1. Note that determination of the similarity of systems must include the nitrogen levels of the systems.

8.1.4.5.4 Default factors

The following default factors[18] may be used for the estimation of $GHG_{BSL\text{-}soil\text{-}N2O,i,t}$ in the absence of data suitable for using the published value approach. Use of a default factor is only permitted for the systems listed below, except where the project area receives hydrologically direct inputs from a point or non-point source of nitrogen such as wastewater effluent or an intensively nitrogen-fertilized system.

For open water systems where the salinity average or salinity low point is >18 ppt:

$$GHG_{BSL\text{-}soil\text{-}N2O,i,t} = 0.000157 \text{ t } N_2O \text{ ha}^{-1} \text{ yr}^{-1} \times N_2O\text{-}GWP \quad \textbf{(45)}$$

For open water systems where the salinity average or salinity low point is >5 and ≤18 ppt:

$$GHG_{BSL\text{-}soil\text{-}N2O,i,t} = 0.00033 \text{ t } N_2O \text{ ha}^{-1} \text{ yr}^{-1} \times N_2O\text{-}GWP \quad \textbf{(46)}$$

For other open water systems:

$$GHG_{BSL\text{-}soil\text{-}N2O,i,t} = 0.00053 \text{ t } N_2O \text{ ha}^{-1} \text{ yr}^{-1} \times N_2O\text{-}GWP \quad \textbf{(47)}$$

For non-seagrass wetland systems where the salinity average or salinity low point is >18 ppt:

$$GHG_{BSL\text{-}soil\text{-}N2O,i,t} = 0.000487 \text{ t } N_2O \text{ ha}^{-1} \text{ yr}^{-1} \times N_2O\text{-}GWP \quad \textbf{(48)}$$

For non-seagrass wetland systems where the salinity average or salinity low point is >5 and ≤18 ppt:

$$GHG_{BSL\text{-}soil\text{-}N2O,i,t} = 0.000754 \text{ t } N_2O \text{ ha}^{-1} \text{ yr}^{-1} \times N_2O\text{-}GWP \quad \textbf{(49)}$$

For other non-seagrass wetland systems:

$$GHG_{BSL\text{-}soil\text{-}N2O,i,t} = 0.000864 \text{ t } N_2O \text{ ha}^{-1} \text{ yr}^{-1} \times N_2O\text{-}GWP \quad \textbf{(50)}$$

Procedures for measuring the salinity average and salinity low point are set out in Section 9.3.8 below.

8.1.4.5.5 Modeling

A quantitative model which meets the requirements set out in Section 8.1.4.1 above may also be used to estimate N_2O emissions from the SOC pool.

8.1.4.5.6 Emission factors

The most recently published IPCC emission factors may also be used to estimate N_2O emissions

---

[18] Taken from Smith *et al.* 1983.

from the SOC pool. Tier 1 values may also be used, but must be applied conservatively following the guidance set out in Section 8.1.4.1 above.

8.1.5 Emissions from fossil fuel use in baseline scenario

Emissions from the use of vehicles and mechanical equipment in the baseline scenario ($GHG_{BSL\text{-}fuel,i,t}$) may be conservatively excluded. However, these emissions in the baseline scenario may be estimated using the procedures set out in Section 8.2.6 below.

8.2 Project Emissions

8.2.1 General approach

Emissions in the project scenario are attributed to carbon stock changes in biomass carbon pools, soil processes, or a combination of these. In addition, where relevant, emissions from organic soil burns and fossil fuel use may be quantified.

Organic soil combustion due to anthropogenic fires is addressed using a conservative default factor (*Fire Reduction Premium*) that is expressed as a proportion of the CO_2 emissions avoided through rewetting (see Section 8.3).

Emissions in the project scenario are estimated as:

$$GHG_{WPS} = GHG_{WPS\text{-}biomass} + GHG_{WPS\text{-}soil} + GHG_{WPS\text{-}burn} + GHG_{WPS\text{-}fuel} \quad \textbf{(51)}$$

$$GHG_{WPS-biomass} = -\sum_{t=1}^{t^*} \sum_{i=1}^{M_{WPS}} \left(\frac{44}{12} \times \Delta C_{WPS-biomass,i,t} \right) \quad \textbf{(52)}$$

$$GHG_{WPS-soil} = \sum_{t=1}^{t^*} \sum_{i=1}^{M_{WPS}} GHG_{WPS-soil,i,t} \quad \textbf{(53)}$$

$$GHG_{WPS-burn} = \sum_{t=1}^{t^*} \sum_{i=1}^{M_{WPS}} GHG_{WPS-burn,i,t} \quad \textbf{(54)}$$

$$GHG_{WPS-fuel} = \sum_{t=1}^{t^*} \sum_{i=1}^{M_{WPS}} GHG_{WPS-fuel,i,t} \quad \textbf{(55)}$$

Where:

GHG_{WPS}	Net CO_2e emissions in the project scenario up to year t^*; t CO_2e
$GHG_{WPS\text{-}biomass}$	Net CO_2e emissions from biomass carbon pools in the project scenario up to year t^*; t CO_2e
$GHG_{WPS\text{-}soil}$	Net CO_2e emissions from the SOC pool in the project scenario up to year t^*; t

	CO_2e
$GHG_{WPS\text{-}burn}$	Net CO_2e emissions from prescribed burning in the project scenario up to year *t**; t CO_2e
$GHG_{WPS\text{-}fuel}$	Net CO_2e emissions from fossil fuel use in the project scenario up to year *t**; t CO_2e
$\Delta C_{WPS\text{-}biomass,i,t}$	Net carbon stock change in biomass carbon pools in the project scenario in stratum *i* in year *t*; t C yr^{-1}
$GHG_{WPS\text{-}soil,i,t}$	GHG emissions from the SOC pool in the project scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
$GHG_{WPS\text{-}burn,i,t}$	GHG emissions from prescribed burning in the project scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
$GHG_{WPS\text{-}fuel,i,t}$	GHG emissions from fossil fuel use the project scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
i	1, 2, 3 …M_{WPS} strata in the project scenario
t	1, 2, 3, … *t** years elapsed since the project start date

Ex-ante estimates of GHG_{WPS} must be based on a project scenario that is defined *ex ante*, and must be projected using the latest version of VCS module *VMD0019 Methods to Project Future Conditions*.

Ex-post estimates of GHG_{WPS} must be based on monitoring results.

8.2.2 Accounting for sea level rise

See Section 8.1.2 for procedures for accounting for sea level rise, noting that for the project scenario, the project proponent may conservatively assume that all eroded carbon is oxidized, or may justify a smaller oxidation rate based on appropriate scientific research.

8.2.3 Net carbon stock change in biomass carbon pools in project scenario

Net carbon stock change in biomass carbon pools in the project scenario is estimated as:

$$\Delta C_{WPS\text{-}biomass,i,t} = \Delta C_{WPS\text{-}tree/shrub,i,t} + \Delta C_{WPS\text{-}herb,i,t} \quad \textbf{(56)}$$

Where:

$\Delta C_{WPS\text{-}biomass,i,t}$	Net carbon stock change in biomass carbon pools in the project scenario in stratum *i* in year *t*; t C yr^{-1}
$\Delta C_{WPS\text{-}tree/shrub,i,t}$	Net carbon stock change in tree and shrub carbon pools in the project scenario in stratum *i* in year *t*; t C yr^{-1}
$\Delta C_{WPS\text{-}herb,i,t}$	Net carbon stock change in herb carbon pools in the project scenario in stratum *i* in year *t*; t C yr^{-1}
i	1, 2, 3 …M_{WPS} strata in the project scenario

t	1, 2, 3, … t^* years elapsed since the project start date

Trees and shrubs

The net carbon stock change in trees and shrubs in the project scenario are estimated using CDM tool *AR-Tool14 Estimation of carbon stocks and change in carbon stocks of trees and shrubs in A/R CDM project activities*, noting that the following equation applies:

$$\Delta C_{WPS\text{-}tree/shrub,i,t} = 12/44 \times (\Delta C_{TREE\_PROJ,t} + \Delta C_{SHRUB\_PROJ,t}) \quad \textbf{(57)}$$

Where:

$\Delta C_{BSL\text{-}tree/shrub,i,t}$	Net carbon stock change in tree and shrub carbon pools in the project scenario in stratum i in year t; t C yr^{-1}
$\Delta C_{TREE\_PROJ,t}$	Change in carbon stock in tree biomass in the project scenario in year t; t CO_2-e yr^{-1} (derived from application of *AR-Tool14*; calculations are done for each stratum i)
$\Delta C_{SHRUB\_PROJ,t}$	Change in carbon stock in shrub biomass in the project scenario in year t; t CO_2-e yr^{-1} (derived from application of *AR-Tool14*; calculations are done for each stratum i)

For the *ex-ante* estimation of tree biomass, an IPCC default factor[19] may be used.

Where reforestation or revegetation activities in the project scenario include harvesting, the maximum number of GHG credits generated by these activities must not exceed the long-term average GHG benefit from the tree component.

For strata where harvesting occurs, the maximum carbon stock in tree biomass ($C_{TREE,i,t}$) used in *AR-Tool14* is limited to $C_{AVG\text{-}TREE,i}$, calculated as follows:

$$C_{AVG-TREE,i} = \frac{\sum_{t=1}^{n} C_{TREE,i,t}}{n} \quad \textbf{(58)}$$

Where:

$C_{AVG\text{-}TREE,i}$	Long-term average carbon stock in baseline or project tree biomass within the project area (in stratum i) in time period n; t CO_2-e
$C_{TREE,i,t}$	Carbon stock in baseline or project tree biomass within the project area (in stratum i) in year t (derived from application of *AR-Tool14*); t CO_2-e yr^{-1}
i	1, 2, 3 …M_{WPS} strata in the project scenario
t	1, 2, 3 … n years elapsed since the project start date

[19] 2013 Supplement to the 2006 Guidelines: Wetlands (Table 4.4). This value can only be used until biomass stock in Table 4.3 of the guidelines is reached.

n	Total number of years in the established time period

The long-term average carbon stock must be calculated for both the baseline and the project scenario.

For projects undertaking even-aged management, the time period *n* over which the long-term average GHG benefit is calculated includes at minimum one full harvest/cutting cycle, including the last harvest/cut in the cycle. For projects under conservation easements with no intention to harvest after the project crediting period (which must be shown in the project description based on verifiable information), or in case of selective cutting, the time period *n* over which the long-term average is calculated is the length of the project crediting period.

Projects may account for long-term carbon storage in wood products. In this case, the parameter $C_{TREE,t}$ in equation 58 must be read as $C_{TREE,i,t}$ + $C_{WP,i,t}$. Procedures for the calculation of $C_{WP,i,t}$ are provided in Appendix 1.

Examples of how to calculate the long-term average carbon benefit are provided in VCS document *AFOLU Guidance: Example for Calculating the Long-Term Average Carbon Stock for ARR Projects with Harvesting.*

Biomass may be lost due to subsidence following sea level rise. For strata where conversion to open water is expected before t = 100, the maximum stock in tree and shrub biomass ($C_{TREE,i,t}$ *and* $C_{SHRUB,t}$*, respectively) used in AR-Tool14* is limited to $C_{AVG-TREE,i}$, *as calculated in equation 58*.

Restoration projects which include afforestation or reforestation components may account for long-term carbon storage in wood products in case trees are harvested before dieback. In this case, the parameter $C_{TREE,t}$ in equation 58 must be read as $C_{TREE,i,t}$ + $C_{WP,i,t}$.

$C_{AVG-SHRUB,i}$ is calculated as follows:

$$C_{AVG-SHRUB,i} = \frac{\sum_{t=1}^{n} C_{SHRUB,i,t}}{n} \quad \textbf{(59)}$$

Where:

$C_{AVG-SHRUB,i}$	Long-term average carbon stock in baseline or project shrub biomass within the project area (in stratum *i*) in time period *n*; t CO_2-e
$C_{SHRUB,i,t}$	Carbon stock in baseline or project shrub biomass within the project area (in stratum *i*) in year *t* (derived from application of *AR-Tool14*); t CO_2-e yr^{-1}
i	1, 2, 3 …M_{WPS} strata in the project scenario
t	1, 2, 3 … *n* years elapsed since the project start date
n	Total number of years in the established time period

Herbaceous vegetation

The net carbon stock change in herbaceous vegetation biomass in the project scenario is estimated using a carbon stock change approach as follows:

$$\Delta C_{WPS\text{-}herb,i,t} = (C_{WPS\text{-}herb,i,t} - C_{WPS\text{-}herb,i,,(t\text{-}T)}) / T \quad \textbf{(60)}$$

Where:

$\Delta C_{WPS\text{-}herb,i,t}$	Net carbon stock changes in herb carbon pools in the project scenario in stratum *i* in year *t*; t C yr^{-1}
$C_{WPS\text{-}herb,i,t}$	Carbon stock in herbaceous vegetation in the project scenario in stratum *i* in year *t*; t C ha^{-1}
i	1, 2, 3 …M_{WPS} strata in the project scenario
t	1, 2, 3 … *t** years elapsed since the start of the project activity
T	Time elapsed between two successive estimations (T=$t_2 - t_1$)

A default factor for $C_{WPS\text{-}herb,i,t}$ of 3 t C ha^{-1} (see Section 8.1.3) may be applied for strata with 100 percent herbaceous cover. For areas with a vegetation cover <100 percent, a 1:1 relationship between vegetation cover and $C_{WPS\text{-}herb,i,t}$ must be applied. The default factor may be claimed only for the first year of the project crediting period as herbaceous biomass quickly reaches a steady state. Vegetation cover must be determined by commonly used techniques in field biology. Procedures for measuring carbons stocks in herbaceous vegetation are provided in Section 9.3.6. The above default factor may not be applied in case *AR-Tool14* is used.

Where the carbon stock change in herbaceous vegetation is quantified in the project scenario, it must also be quantified in the baseline scenario.

8.2.4 Net GHG emissions and removals from soil in project scenario

8.2.4.1 General

Net GHG emissions from soils in the project scenario are estimated as:

$$GHG_{WPS\text{-}soil,i,t} = A_{i,t} \times (GHG_{WPS\text{-}soil\text{-}CO2,i,t} - Deduction_{alloch} + GHG_{WPS\text{-}soil\text{-}CH4,i,t} + GHG_{WPS\text{-}soil\text{-}N2O,i,t})^{(20)} \quad \textbf{(61)}$$

Where:

$GHG_{WPS\text{-}soil,i,t}$	GHG emissions from the SOC pool in the project scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
$GHG_{WPS\text{-}soil\text{-}CO2,i,t}$	CO_2 emissions from the SOC pool in the project scenario in stratum *i* in year *t*; t CO_2e ha^{-1} yr^{-1}
$Deduction_{alloch}$	Deduction from CO_2 emissions from the SOC pool to account for the

[20] This equation only applies if $GHG_{WPS\text{-}soil\text{-}CO2,i,t}$ is negative (sequestration).

	percentage of the carbon stock that is derived from allochthonous soil organic carbon; t CO_2e ha^{-1} yr^{-1}
$GHG_{WPS-soil-CH4,i,t}$	CH_4 emissions from the SOC pool in the project scenario in stratum *i* in year *t*; t CO_2e ha^{-1} yr^{-1}
$GHG_{WPS-soil-N2O,i,t}$	N_2O emissions from the SOC pool in the project scenario in stratum *i* in year *t*; t CO_2e ha^{-1} yr^{-1}
$A_{i,t}$	Area of stratum *i* in year *t*; ha
i	1, 2, 3 …M_{WPS} strata in the project scenario
t	1, 2, 3, … *t** years elapsed since the project start date

8.2.4.2 CO_2 emissions from soil

CO_2 emissions from soils may be estimated using one of the following approaches:

1) Proxies;
2) Published values;
3) Default factors;
4) Models; or
5) Field-collected data.

In certain cases allochthonous soil organic carbon may accumulate in the project area, and such carbon must be accounted for in the project scenario. Procedures for the estimation of a compensation factor for allochthonous soil organic carbon are specified in Sections 8.1.4.3 and 8.2.4.2.2.

8.2.4.2.1 Approaches for estimating $GHG_{WPS-soil-CO2,i,t}$

$GHG_{WPS-soil-CO2,i,t}$ must be calculated using the same procedures set out in Sections 8.1.4.2.1 – 8.1.4.2.6 above. For all equations in these sections, the subscript *BSL* must be substituted by *WPS* to make clear that the relevant values are being quantified for the project scenario.

8.2.4.2.2 Deduction for allochthonous carbon

A deduction must be applied to account for allochthonous carbon using the procedures set out in Section 8.1.4.3. The project proponent must also follow the additional guidance below.

The determination of the deduction for allochthonous carbon is mandatory for the project scenario unless the project proponent is able to demonstrate that the allochthonous carbon would have been returned to the atmosphere in the form of carbon dioxide in the absence of the project.

The deduction for allochthonous carbon must only be applied to soil layers deposited or accumulated after the project start date (such as materials formed above a feldspar marker horizon).

If the organic surface layer exceeds 10 cm, the soil is deemed organic and no deduction is required. If an organic surface layer of up to 10 cm is present, *deduction_alloch* must be determined only in such cases where the project experiences mineral sedimentation events sufficient to create mineral soil layers. In practice, the project area may show mineral sedimentation in places. If this is observed it is assumed that at some point during the project crediting period mineral sediment can be deposited on top of organic surface layers, unless the project proponent can justify that strata with an organic surface layer of less than 10 cm will not experience mineral sedimentation during the project crediting period.

8.2.4.3 CH_4 emissions from soil

The estimation of CH_4 emissions in project scenario must follow one of the approaches provided in Section 8.1.4.4 above. For all equations in these sections, the subscript *BSL* must be substituted by *WPS* to make clear that the relevant values are being quantified for the project scenario.

8.2.4.4 N_2O emissions from soil

Where the project proponent is able to demonstrate (eg, by referring to peer-reviewed literature based on similar project circumstances[21]) that N_2O emissions do not increase in the project scenario compared to the baseline scenario, N_2O emissions may be excluded.

N_2O emissions must be accounted for in the project scenario in strata where water levels were lowered as a result of project activities[22]. Seagrass restoration projects do not require N_2O emission accounting. The estimation of N_2O emissions in the project scenario may follow one of the approaches provided in Section 8.1.4.5. For all equations in these sections, the subscript *BSL* must be substituted by *WPS* to make clear that the relevant values are being quantified for the project scenario.

In addition, where the project proponent is able to demonstrate (eg, by referring to peer-reviewed literature) that N_2O emissions in the project scenario are *de minimis*, N_2O emissions may be excluded. To demonstrate that N_2O emissions are *de minimis* in the project scenario, the project proponent must use CDM tool *Tool for testing significance of GHG emissions in A/R CDM project activities*, or refer to peer-reviewed literature.

---

[21] Project circumstances are defined by pre-project land use (eg, forestry, agriculture, abandonment after such activities) and its intensity (especially related to N-fertilization), climatic zone, water table depths, and soil type.

[22] See applicability conditions.

8.2.5 Net non-CO_2 emissions from prescribed burning in project scenario

Where the project proponent introduces prescribed burning of shrub and herbaceous biomass, the project proponent must a) demonstrate that the project does not decrease carbon sequestration rates if using the default factor approach for carbon dioxide emissions accounting from soil, and b) account for CH_4 and N_2O emissions as follows:

$$GHG_{WPS\text{-}burn,i,t} = CO_2e_{N2O,i,t} + CO_2e_{CH4,i,t} \quad \textbf{(62)}$$

$$CO_2e_{N2O,i,t} = Biomass_{i,t} \times EF_{N2O,burn} \times N_2O\text{-}GWP \times 10^{-6} \times A_{i,t} \quad \textbf{(63)}$$

$$CO_2e_{CH4,i,t} = Biomass_{i,t} \times EF_{CH4,burn} \times CH_4\text{-}GWP \times 10^{-6} \times A_{i,t} \quad \textbf{(64)}$$

Where:

$GHG_{WPS\text{-}burn,i,t}$	GHG emissions from prescribed burning in the project scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
$CO_2e_{N2O,i,t}$	CO_2e emissions resulting from N_2O emissions due to prescribed burning in stratum *i* in year *t*; t CO_2e yr^{-1}.
$CO_2e_{CH4,i,t}$	CO_2e emissions resulting from CH_4 emissions due to prescribed burning in stratum *i* in year *t*; t CO_2e yr^{-1}.
$Biomass_{i,t}$	Aboveground shrub and herbaceous biomass in stratum *i* in year *t* (from Section 8.2.3), kg d.m. ha^{-1}
$EF_{N2O,burn}$	Emission factor for N_2O for vegetation burning; g N_2O / kg dry biomass
$EF_{CH4,burn}$	Emission factor for CH_4 for vegetation burning; g CH_4 / kg dry biomass
$N_2O\text{-}GWP$	Global warming potential of N_2O; dimensionless
$CH_4\text{-}GWP$	Global warming potential of CH_4; dimensionless
$A_{i,t}$	Area of stratum *i* in year *t;* ha
i	1, 2, 3 …M_{WPS} strata in the project scenario
t	1, 2, 3, … *t** years elapsed since the project start date

8.2.6 Emissions from fossil fuel use

Where emissions from the use of vehicles and mechanical equipment for earth moving in WRC project activities are above *de minimis* as compared to the baseline scenario, such emissions must be estimated by applying CDM tool *Estimation of GHG emissions related to fossil fuel combustion in A/R CDM project activities*, noting that the following equation applies:

$$GHG_{WPS\text{-}fuel,i,t} = ET_{FC,y} \quad \textbf{(65)}$$

Where:

$GHG_{WPS\text{-}fuel,i,t}$	GHG emissions from fossil fuel use in the project scenario in stratum *i* in year *t*; t CO_2e yr^{-1}

$ET_{FC,y}$	CO_2 emissions from fossil fuel combustion during the year *y*; t CO_2 (derived from application of CDM tool *Estimation of GHG emissions related to fossil fuel combustion in A/R CDM project activities*; calculations are done for each stratum *i*)
i	1, 2, 3 …M_{WPS} strata in the project scenario
t	1, 2, 3, … *t** years elapsed since the project start date

The tool has been designed for A/R CDM project activities, but must be used for the purposes of this methodology, noting the following:

Where the tool refers to:	It must be understood as referring to:
A/R	WRC
CDM	VCS
DOE	VVB

8.3 Emission reductions due to rewetting and fire management (Fire Reduction Premium)

This methodology addresses the emission reductions generated from reduced anthropogenic fires occurring in drained organic soils due to rewetting and fire management. Emission reductions are estimated using a conservative default factor which is based on fire occurrence and extension in the project area in the baseline scenario. This method avoids the need for direct assessment of GHG emissions from fire in the baseline and the project scenarios. The project proponent must apply the latest version of VCS module *VMD0046 Methods for monitoring soil carbon stock changes and GHG emissions in WRC project activities* to estimate of the *Fire Reduction Premium* (*FRP*).

For each stratum with organic soil to which the project proponent applies the approach, the parameters $E_{peatsoil\text{-}WPS,i,t}$ (Greenhouse gas emissions from the peat soil within the project boundary in the project scenario in stratum *i* in year *t* (t CO_2e yr^{-1})) and $E_{peatsoil\text{-}BSL,i,,t}$ (GHG emissions from microbial decomposition of the peat soil within the project boundary in the baseline scenario in stratum *i* in year *t* (t CO_2e yr^{-1})) in the module are obtained from $GHG_{WPS\text{-}soil,i,t}$ and $GHG_{BSL\text{-}soil,i,t}$.

8.4 Leakage

8.4.1 Activity-shifting leakage and market leakage

The applicability conditions of this methodology are structured to ensure that activity-shifting leakage and market leakage do not occur. As such, where the applicability conditions of this methodology are met, activity-shifting leakage and market leakage may be assumed to be zero.

8.4.2 Ecological leakage

It may be assumed that ecological leakage does not occur in projects meeting the applicability conditions of this methodology, because projects must be designed in a manner which ensures that their hydrological connectivity with adjacent areas does not lead to a significant increase in GHG emissions outside the project area. This may be achieved by a project design which causes no alteration of mean annual water table depths or flooding frequency or duration in adjacent areas, or limiting such alteration to levels that do not influence GHG emissions. Where, at the design stage, hydrological changes are expected to impact GHG emissions in areas outside the project area, the project design must be adjusted to include such areas in the project area.

The project proponent must demonstrate that their project design meets these requirements through expert judgment, hydrologic modeling or monitoring of alterations of water table depth at the project area. In tidal wetland restoration projects, de-watering downstream wetlands is not expected if project areas are set sufficiently large to include expected areas of changed hydrology.

Hydrologic models must consider water displacement from project activities and the hydrologic connection or blockage of inlets that would change the wetland boundary. Procedures for monitoring alterations of water table depth at the project area are provided in Section 9.3.4.

The tidal range and sediment delivery experienced by wetlands outside the project area must remain within the system tolerance, which is defined by the high and low tides and regional sediment budget, and assessed using hydrological models (and/or empirical analysis) and expert judgment.

To guide this assessment, Table 8.1 outlines avoidance criteria related to a variety of processes that may occur outside the project area due to an inappropriate project design.

Table 8.1 Processes Associated with Ecological Leakage Outside Project Boundary and Related Criteria for their Avoidance

Ecological leakage process outside project boundary	Avoidance criterion
Lowering water table that causes increased soil carbon oxidation	Maintain wetland conditions (eg, converting from impounded water to a wetland does not cause soil oxidation)
Lowering water table that causes increased N_2O emissions	No conversion of non-seagrass wetland to open water
Raising water table that causes increased CH_4 emissions	No conversion of non-wetland to wetland

Raising water table that causes decreased vegetation production that causes decreased new soil carbon sequestration	No causation of vegetated to non-vegetated (or poorly vegetated) conditions

Projects meeting the requirements of this Section 8.4 may assume that GHG_{LK} = 0.

8.5 Net GHG Emission Reduction and Removals

8.5.1 Calculation of net GHG emissions reductions

The total net GHG emission reductions from the RWE project activity are calculated as follows:

$$NER_{RWE} = GHG_{BSL} - GHG_{WPS} + FRP - GHG_{LK} \quad \textbf{(66)}$$

Where:

NER_{RWE}	Net CO_2e emission reductions from the RWE project activity; t CO_2e
GHG_{BSL}	Net CO_2e emissions in the baseline scenario; t CO_2e
GHG_{WPS}	Net CO_2e emissions in the project scenario; t CO_2e
FRP	*Fire Reduction Premium* (net CO_2e emission reductions from organic soil combustion due to rewetting and fire management); t CO_2e
GHG_{LK}	Net CO_2e emissions due to leakage; t CO_2e

Long-term benefit in WRC projects

For projects claiming reductions of baseline GHG emissions, the maximum quantity of GHG emission reductions that may be claimed from the SOC pool is limited to the difference between the organic soil carbon stock in the project scenario and baseline scenario after a 100-year time frame. Procedures for estimating this difference in stratum *i* at *t* = 100 ($C_{WPS\text{-}BSL,i,t100}$) are provided in Section 5.2.4. The component $GHG_{BSL\text{-}soil\text{-}CO2,i,t}$ - $GHG_{WPS\text{-}soil\text{-}CO2,i,t}$ within equation 61 must be capped as follows:

$$GHG_{BSL-soil-CO2,i,t} - GHG_{WPS-soil-CO2,i,t} \le \frac{44}{12} \times C_{WPS-BSL,t100} \quad \textbf{(67)}$$

Where:

$GHG_{BSL\text{-}soil\text{-}CO2,i,t}$	CO_2 emissions from the SOC pool in the baseline scenario in stratum *i* in year *t*; t CO_2e ha^{-1} yr^{-1}
$GHG_{WPS\text{-}soil\text{-}CO2,i,t}$	CO_2 emissions from the SOC pool in the project scenario in stratum *i* in year *t*; t CO_2e ha^{-1} yr^{-1}
$C_{WPS\text{-}BSL,t100}$	Difference between organic soil carbon stock in the project scenario and baseline scenario at *t*=100; t C ha^{-1}

Note also that NER_{RWE} must be corrected for uncertainty by estimating the total uncertainty for the RWE project activity (NER_{RWE_ERROR}) using the procedures set out in Section 8.5.2 below.

8.5.2 Estimation of uncertainty

The following procedure allows the project proponent to estimate uncertainty in the estimation of emissions and carbon stock changes (ie, for calculating a precision level and any deduction in credits for lack of precision following project implementation and monitoring) by assessing uncertainty in baseline and project estimations.

This procedure focuses on the following sources of uncertainty:

- Uncertainty associated with estimation of stocks in carbon pools and changes in carbon stocks
- Uncertainty in assessment of project emissions

Where an uncertainty value is not known or cannot be calculated, the project proponent must justify that it is using a conservative number and an uncertainty of 0 percent may be used for this component.

Uncertainty guidance

A precision target of a 90 percent or 95 percent confidence interval equal to or less than 20 percent or 30 percent, respectively, of the recorded value must be targeted. This is especially important in terms of project planning for measurement of carbon stocks where sufficient measurement plots should be included to achieve this precision level across the measured stocks.

Levels of uncertainty must be known for all aspects of baseline and project implementation and monitoring. Uncertainty will generally be known as the 90 percent or 95 percent confidence interval expressed as a percentage of the mean. Where uncertainty is not known, it must be demonstrated that the value used is conservative.

Estimated carbon emissions and removals arising from AFOLU activities have uncertainties associated with the measures and estimates of several parameters. These include the project area or other activity data, carbon stocks, biomass growth rates, expansion factors and other coefficients. It is assumed that the uncertainties associated with the estimates of the various input data are available, either as default factors given in IPCC Guidelines (2006), IPCC GPG-LULUCF (2003), expert judgment or estimates based of sound statistical sampling.

Alternatively, conservative estimates may also be used instead of uncertainties, provided that they are based on verifiable literature sources or expert judgment. In this case the uncertainty is assumed to be zero. However, these procedures combine uncertainty information and conservative estimates resulting in an overall *ex-post* project uncertainty.

Planning to diminish uncertainty

It is important that the process of project planning consider uncertainty. Procedures including stratification and the allocation of sufficient measurement plots help ensure that low uncertainty in carbon stocks results and ultimately full crediting can result.

It is good practice to apply this procedure at an early stage to identify the data sources with the highest uncertainty to allow the opportunity to conduct further work to diminish uncertainty.

Note that in Parts 1 – 3 below the denominators of the equations must be expressed in absolute values.

Part 1 – Uncertainty in baseline estimates

$$Uncertain_{BSL,i} = \frac{\sqrt{\left(U_{BSL,SS1,i} * E_{BSL,SS1,i}\right)^2 + \left(U_{BSL,SS2,i} * E_{BSL,SS2,i}\right)^2 ... + ...\left(U_{BSL,SSn,i} * E_{BSL,SSn,i}\right)^2}}{E_{BSL,SS1,i} + E_{BSL,SS2,i} ... + ...E_{BSL,SSn,i}} \quad \textbf{(68)}$$

Where:

$Uncertain_{BSL,i}$	Percentage uncertainty in the combined carbon stocks and GHG sources in the baseline scenario in stratum *i*; %
$U_{BSL,SS,i}$	Percentage uncertainty (expressed as 90 percent confidence interval as a percentage of the mean, where appropriate) for carbon stocks and GHG sources in the baseline scenario in stratum *i* (1,2…n represent different carbon pools and/or GHG sources); %
$E_{BSL,SS,i}$	Carbon stock or GHG sources (eg, trees, down dead wood) in stratum *i* (1,2…n represent different carbon pools and/or GHG sources) in the baseline scenario; t CO_2e
i	1, 2, 3 …M_{BSL} strata in the baseline scenario

To assess uncertainty across combined strata, use the equation below:

$$Uncertain_{BSL} = \frac{\sqrt{\left(U_{BSL,1} * A_1\right)^2 + \left(U_{BSL,2} * A_2\right)^2 ... + ...\left(U_{BSL,M_{BSL}} * A_{M_{BSL}}\right)^2}}{A_1 + A_2 ... + ...A_{M_{BSL}}} \quad \textbf{(69)}$$

Where:

$Uncertain_{BSL}$	Total uncertainty in baseline scenario; %
$U_{BSL,i}$	Uncertainty in baseline scenario in stratum *i*; %
A_i	Area of stratum *i*; ha
i	1, 2, 3 …M_{BSL} strata in the baseline scenario

Part 2 – Uncertainty ex-post in the project scenario

$$Uncertain_{WPS,i} = \frac{\sqrt{\left(U_{WPS,SS1,i} * E_{WPS,SS1,i}\right)^2 + \left(U_{WPS,SS2,i} * E_{WPS,SS2,i}\right)^2 ... + ...\left(U_{WPS,SSn,i} * E_{WPS,SSn,i}\right)^2}}{E_{WPS,SS1,i} + E_{WPS,SS2,i} ... + ... E_{WPS,SSn,i}} \quad \textbf{(70)}$$

Where:

$Uncertain_{WPS,i}$	Percentage uncertainty in the combined carbon stocks and GHG sources in the project scenario in stratum *i*; %
$U_{WPS,SS,i}$	Percentage uncertainty (expressed as 90 percent confidence interval as a percentage of the mean, where appropriate) for carbon stocks and GHG sources in the project scenario in stratum *i* (1,2…n represent different carbon pools and/or GHG sources); %
$E_{WPS,SS,i}$	Carbon stock or GHG sources (eg, trees, down dead wood, etc.) in stratum *i* (1,2…n represent different carbon pools and/or GHG sources) in the project scenario; t CO_2e
i	1, 2, 3 …M_{WPS} strata in the project scenario

To assess uncertainty across combined strata, use the equation below:

$$Uncertain_{WPS} = \frac{\sqrt{\left(U_{WPS,1} * A_1\right)^2 + \left(U_{WPS,2} * A_2\right)^2 ... + ...\left(U_{WPS,M_{BSL}} * A_{M_{BSL}}\right)^2}}{A_1 + A_2 ... + ... A_{M_{BSL}}} \quad \textbf{(71)}$$

Where:

$Uncertain_{WPS}$	Total uncertainty in project scenario; %
$U_{WPS,i}$	Uncertainty in project scenario in stratum *i*; %
A_i	Area of stratum *i*; ha
i	1, 2, 3 …M_{WPS} strata in the project scenario

Part 3 – Total error in project activity

$$NER_{ERROR} = \frac{\sqrt{(Uncertain_{BSL} \times GHG_{BSL})^2 + (Uncertain_{WPS} \times GHG_{WPS})^2}}{GHG_{BSL} + GHG_{WPS}} \quad \textbf{(72)}$$

Where:

NER_{ERROR}	Total uncertainty for project activity; %
$Uncertain_{BSL}$	Total uncertainty in baseline scenario; %
$Uncertain_{WPS}$	Total uncertainty in the project scenario; %
GHG_{BSL}	Net CO_2e emissions in the baseline scenario up to year *t**; t CO_2e
GHG_{WPS}	Net CO_2e emissions in the project scenario up to year *t**; t CO_2e

The allowable uncertainty is 20 percent or 30 percent of NER_t at a 90 percent or 95 percent confidence level, respectively. Where this precision level is met, no deduction must result for uncertainty. Where this precision level is exceeded, a deduction equal to the amount that the uncertainty exceeds the allowable level must be applied. The adjusted value for NER_t to account for uncertainty must be calculated as:

$$adjusted\_NER_t = NER_t \times (100\% - NER_{ERROR} + allowable\_uncert) \quad \textbf{(73)}$$

Where:

$adjusted\_NER_t$	Net GHG emission reductions in year *t* adjusted to account for uncertainty; t CO_2e
NER_t	Total net GHG emission reductions from the project activity up to year *t*; t CO_2e
NER_{ERROR}	Total uncertainty for WRC project activity; %
allowable_unsert	Allowable uncertainty; 20 percent or 30 percent at a 90 percent or 95 percent confidence level, respectively; %

8.5.3 Calculation of Verified Carbon Units

In order to calculate the number of Verified Carbon Units (VCUs) that may be issued, the project proponent must consider the number of buffer credits which must be deposited in the AFOLU pooled buffer account. The number of buffer credits which must be deposited in the AFOLU pooled buffer account is based on the net change in carbon stocks.

The number of verified carbon units (VCUs) is calculated as:

$$VCU_{t2} = \left(adjusted\_NER_{t2} - adjusted\_NER_{t1}\right) - Bufferw_{t2} \quad \textbf{(74)}$$

Where:

VCU_{t2}	Number of VCUs in year *t2*
$adjusted\_NER_{t1}$	Total net GHG emission reductions from the project activity up to year *t1* adjusted to account for uncertainty; t CO_2e
$adjusted\_NER_{t2}$	Total net GHG emission reductions from the project activity up to year *t2* adjusted to account for uncertainty; t CO_2e
$Bufferw_{t2}$	Number of buffer credits to be contributed to the AFOLU pooled buffer account in year *t2*

$$Bufferw_{t2} = \left(NER_{stock,t2} - NER_{stock,t1}\right) \times Buffer\%_{t2} \quad \textbf{(75)}$$

Where:

$Bufferw_{t2}$	Number of buffer credits to be contributed to the AFOLU pooled buffer account in year *t2*
$NER_{stock,\ t1}$	Net GHG emission reductions from the project activity up to year *t1*, discarding

non-CO_2 emissions from soil and biomass burning and emissions from fossil fuel use; t CO_2e

$NER_{stock,\ t2}$ Net GHG emission reductions from the project activity up to year *t2*, discarding non-CO_2 emissions from soil and biomass burning and emissions from fossil fuel use; t CO_2e

$Buffer\%_{t2}$ Percentage of buffer credits to be contributed to the AFOLU pooled buffer account in year *t2*; %

The percentage of buffer credits to be contributed to the AFOLU pooled buffer account must be determined by applying the latest version of the *VCS AFOLU Non-Permanence Risk Tool*.

9 MONITORING

9.1 Data and Parameters Available at Validation

Data / Parameter	$Depth_{peat,i,t0}$
Data unit	m
Description	Average organic soil depth above the drainage limit in stratum *i* at the project start date; m
Equations	1, 7, 8
Source of data	Direct measurement or literature involving the project area or similar areas
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	Organic soil depths at the project start date may be derived from: • Surface height measurements relative to a fixed reference point in m asl (eg, using poles fixed in the underlying mineral soil or rock) within the project area; where relevant in combination with gauge measurement of the water table to determine the drainage limit • Literature involving the project area or similar areas
Purpose of data	Calculation of baseline emissions Calculation of the maximum quantity of GHG emission reductions that may be claimed by the project
Comments	Reassessed when baseline is reassessed

Data / Parameter	$Rate_{peatloss\text{-}BSL,i}$
Data unit	m yr^{-1}
Description	Rate of organic soil loss due to subsidence and fire in the baseline scenario in stratum *i*

Equations	1, 7, 13
Source of data	The rate of organic soil loss due to subsidence must be based on verifiable information and may be derived from: 1) Expert judgment, datasets and/or literature of historic subsidence involving the project or similar areas. Data must be based on surface height measurements relative to a fixed reference point in m asl, following methods described in Ballhorn *et al*. 2009 (eg, using poles fixed in the underlying mineral soil or rock, or by remote sensing) or similar. Or 2) CO_2 emissions derived from GHG emission proxies (see Section 8.1.4.2.1 above) in combination with data on volumetric carbon content of the organic soil. Divide the annual CO_2 emission (t CO_2 ha^{-1}) by 44/12, then divide by volumetric carbon content (g C cm^{-3}) to obtain height loss in m. The average depth of burn scars may be derived from expert judgment, datasets and/or literature of historic burn depths involving the project or similar areas. Data must be based on surface height measurements, using field measurements or remote sensing (eg, following methods described in Ballhorn *et al*. 2009). The areal extent of burn scars may be obtained from statistics and/or maps in official reports and/or field measurements or remote sensing data. For organic soil loss due to fire, based on the areal extent of burnt and non-burnt areas, a mean annualized burn depth must be calculated and applied to the entire project area. The project proponent must demonstrate, using expert judgment, datasets and/or scientific literature that the accuracy of the derived rate of organic soil loss is sufficient to fulfill the criteria set out in Section 5.2.2 (Stratification). Similarity of areas must be demonstrated (via direct measurements, literature resources, datasets or a combination of these) with respect to organic soil type, climatic conditions, land use (forestry, agriculture, peat extraction, or abandonment after these activities), and average annual water table depth (±20 percent). In case of dissimilarity, the project proponent must demonstrate that such difference gives a conservative result for the net GHG benefits of the project. Forecasting organic soil subsidence rates must be based on the conservative extrapolation of a historic trend, or conservative modeling of proxies such as water table depth and land use type.

Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	See Source of data above
Purpose of data	Calculation of baseline emissions Calculation of the maximum quantity of GHG emission reductions that may be claimed by the project
Comments	In the absence of an accurate value for the determination of PDT, a conservative (high) value may be applied, while for the determination of the maximum quantity of GHG emission reductions which may be claimed from the soil carbon pool, a conservative (low) value may be applied that remains constant over time. The use of a relatively low value for a constant rate of organic soil loss may not be confused with a relatively high value when determining the need for stratification of organic soil depth. Reassessed when baseline is reassessed

Data Unit / Parameter	$Rate_{peatloss\text{-}WPS,i,t}$
Data unit	m yr^{-1}
Description	Rate of organic soil loss due to subsidence in the project scenario in stratum *i* in year *t*
Equations	8
Source of data	The rate of organic soil loss due to subsidence must be based on verifiable information and may be derived from: 1) Expert judgment, datasets and/or literature of subsidence involving areas representing conditions similar to the project. Data must be based on surface height measurements relative to a fixed reference point in m asl, following methods described in Ballhorn *et al*. 2009 (eg, using poles fixed in the underlying mineral soil or rock, or by remote sensing or similar). Or 2) CO_2 emissions derived from GHG emission proxies, see Section 8.1.4.2.1 above, in combination with data on volumetric carbon content of the organic soil. Divide the annual CO_2 emission (t CO_2 ha^{-1}) by 44/12, then divide by volumetric carbon content (g C cm^{-3}) to obtain height loss in m. The project proponent must demonstrate, using expert judgment,

	datasets and/or scientific literature that the accuracy of the derived rate of organic soil loss is sufficient to fulfill the criteria set out in Section 5.2.2 (Stratification). Similarity of areas must be demonstrated (by direct measurements, literature resources, datasets or a combination of these) with respect to organic soil type, climatic conditions, land use (forestry, agriculture, peat extraction, or abandonment after these activities), and average annual water table depth (±20 percent). In case of dissimilarity, the project proponent must demonstrate that such difference gives a conservative result for the net GHG benefits of the project.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	See Source of data above
Purpose of data	Calculation of project emissions Calculation of the maximum quantity of GHG emission reductions that may be claimed by the project
Calculation method	N/A
Comments	In the absence of an accurate value, for the determination of the maximum quantity of GHG emission reductions which may be claimed from the soil carbon pool, a conservative (high) value may be applied that remains constant over time. Reassessed when baseline is reassessed

Data / Parameter	$Rate_{Closs\text{-}BSL,i,t}$
Data unit	t C ha^{-1} yr^{-1}
Description	Rate of organic carbon loss in mineral soil due to oxidation in the baseline scenario in stratum *i* in year *t*
Equations	2, 9, 15
Source of data	May be estimated using published values (see Sections 8.1.4.1 and 8.1.4.2.2) or either historical data collected from the project site or chronosequence data collected at similar sites (see Sections 8.1.4.1 and 8.1.4.2.6). Alternatively, a conservative (low) value may be applied that remains constant over time.
Value applied	N/A

Justification of choice of data or description of measurement methods and procedures applied	Extrapolation of $Rate_{Closs-BSL,i}$ over the entire project crediting period must account for the possibility of a non-linear decrease of soil organic carbon over time, including the tendency of organic carbon concentrations to approach steady-state equilibrium (see Section 5.1)
Purpose of data	Calculation of baseline emissions Calculation of the maximum quantity of GHG emission reductions that may be claimed by the project
Comments	In the absence of an accurate value for the determination of the SDT, a conservative (high) value may be applied, while for the determination of the maximum quantity of GHG emission reductions which may be claimed from the soil carbon pool, a conservative (low) value may be applied that remains constant over time. Reassessed when baseline is reassessed

Data / Parameter	$Rate_{Closs-WPS,i,t}$
Data unit	t C ha^{-1} yr^{-1}
Description	Rate of organic carbon loss in mineral soil due to oxidation in the project scenario in stratum *i* in year *t*
Equations	16
Source of data	N/A
Value applied	0
Justification of choice of data or description of measurement methods and procedures applied	This value is conservatively set to zero as loss rates are likely to be negative. The value must be reassessed when the baseline is reassessed. If at that event there is evidence that SOC has decreased, the calculation must be adjusted using the carbon loss rate to date, unless it can be justified that the carbon loss was temporary.
Purpose of data	Calculation of project emissions Calculation of the maximum quantity of GHG emission reductions that may be claimed by the project
Comments	Reassessed when baseline is reassessed

Data / Parameter	$\Delta C_{TREE\_BSL,t}$
Data unit	t CO_2-e yr^{-1}
Description	Change in carbon stock in baseline tree biomass within the project

	area in year *t*
Equations	23
Source of data	Derived from application of *AR-Tool14*
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	N/A
Purpose of data	Calculation of baseline emissions
Comments	Calculations are done for each stratum *i* Reassessed when baseline is reassessed

Data / Parameter	$\Delta C_{SHRUB\_BSL,t}$
Data unit	t CO_2-e yr^{-1}
Description	Change in carbon stock in baseline shrub biomass within the project area in year *t*
Equations	23
Source of data	Derived from application of *AR-Tool14*
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	N/A
Purpose of data	Calculation of baseline emissions
Comments	Calculations are done for each stratum *i* Reassessed when baseline is reassessed

Data / Parameter	$Rate_{subs\text{-}BSL,i}$
Data unit	m yr^{-1}
Description	Rate of organic soil loss due to subsidence in the baseline scenario in stratum *i*
Equations	28
Source of data	The rate of organic soil loss due to subsidence must be based on verifiable information and may be derived from:

	1) Expert judgment, datasets and/or literature of historic subsidence involving the project or similar areas. Data must be based on surface height measurements relative to a fixed reference point in m asl, following methods described in Ballhorn *et al*. 2009 (eg, using poles fixed in the underlying mineral soil or rock, or by remote sensing) or similar. Or 2) CO_2 emissions derived from GHG emission proxies, see Section 8.1.4.2.1 above, in combination with data on volumetric carbon content of the organic soil. Divide the annual CO_2 emission (t CO_2 ha^{-1}) by 44/12, then divide by volumetric carbon content (g C cm^{-3}) to obtain height loss in m. The average depth of burn scars may be derived from expert judgment, datasets and/or literature of historic burn depths involving the project or similar areas. Data must be based on surface height measurements, using field measurements or remote sensing (eg, following methods described in Ballhorn *et al*. 2009). The areal extent of burn scars may be obtained from statistics and/or maps in official reports and/or field measurements or remote sensing data. The project proponent must demonstrate, using expert judgment, datasets and/or scientific literature that the accuracy of the derived rate of organic soil loss is sufficient to fulfill the criteria set out in Section 5.2.2 (Stratification). Similarity of areas must be demonstrated (via direct measurements, literature resources, datasets or a combination of these) with respect to organic soil type, climatic conditions, land use (forestry, agriculture, peat extraction, or abandonment after these activities), and average annual water table depth (±20 percent). In case of dissimilarity, the project proponent must demonstrate that such difference gives a conservative result for the net GHG benefits of the project. Forecasting organic soil subsidence rates must be based on the conservative extrapolation of a historic trend, or conservative modeling of proxies such as water table depth and land use type.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	See Source of data above and Couwenberg & Hooijer (2013).
Purpose of data	Calculation of baseline emissions

Comments	In the absence of an accurate value, for the determination of subsidence a conservative (low) value may be applied. Reassessed when baseline is reassessed

Data / Parameter	$C_{BSL\text{-}soil,i,t}$
Data unit	t C ha^{-1}
Description	Soil organic carbon stock in the baseline scenario in stratum *i* in year *t*
Equations	29
Source of data	Soil coring may be used to generate a value of $C_{BSL\text{-}soil,i,t}$ as specified in Section 9.3.7
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	For the baseline scenario, soil cores must be collected within 2 years prior to the project start date. Where using an installed reference plane for the baseline scenario, it must have been installed at least 4 years prior to the baseline measurement, which is good practice to ensure that a reliable average accumulation rate is obtained.
Purpose of data	Calculation of baseline emissions
Comments	Reassessed when baseline is reassessed

Data / Parameter	$Depth_{soil,i,t0}$
Data unit	m
Description	Average mineral soil depth in stratum *i* at the project start date
Equations	11
Source of data	Direct measurements and/or literature involving the project area or similar areas
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	Mineral soil depths at the project start date may be derived from direct measurements within the project area or literature involving the project area or similar areas
Purpose of data	Calculation of baseline emissions Calculation of the maximum quantity of GHG emission reductions

	that may be claimed by the project
Comments	N/A

Data / Parameter	*VC*
Data unit	kg C m^{-3}
Description	Volumetric organic carbon content of organic or mineral soil
Equations	5, 6, 11, 13, 14, 15, 16
Source of data	Direct measurements and/or literature involving the project area or similar areas
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	Determined through procedures specified in Section 9.3.7
Purpose of data	Calculation of baseline emissions Calculation of project emissions Calculation of the maximum quantity of GHG emission reductions that may be claimed by the project
Comments	

Data / Parameter	$A_{BSL,i}$ (or $A_{i,t}$)
Data unit	ha
Description	Area of baseline stratum *i* (in year *t*)
Equations	4, 12, (25, 61, 63, 64)
Source of data	Delineation of strata is done preferably using a Geographical Information System (GIS), which allows for integrating data from different sources (including GPS coordinates and remote sensing data).
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	See Source of data above
Purpose of data	Calculation of baseline emissions
Comments	N/A

Data / Parameter	$C_{BSL\text{-}herb,i,t}$
Data unit	t C ha^{-1}
Description	Carbon stock in herbaceous vegetation in the baseline scenario in stratum *i* in year *t*
Equations	22, 24
Source of data	Direct measurements or default factor
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	A default factor[23] of 3 t C ha^{-1} may be applied for strata with 100 percent herbaceous cover. For areas with a vegetation cover <100 percent, a 1:1 relationship between vegetation cover and $C_{BSL,\text{-}herb,i,t}$ must be applied. The default may be claimed for one year only during the project crediting period as herbaceous biomass quickly reaches a steady state. Vegetation cover must be determined by commonly used techniques in field biology. Procedures for measuring carbons stocks in herbaceous vegetation are provided in Section 9.3.6 above.
Purpose of data	Calculation of baseline emissions
Comments	Reassessed when baseline is reassessed

Data / Parameter	*%OM* (or $\%OM_{soil}$)
Data unit	%
Description	Percentage of soil organic matter
Equations	33, 34, 36, 38, 76, 77, 78, 79
Source of data	Direct measurements based on loss-on-ignition or may be derived from direct measurements of soil carbon. These measurements may be made using samples collected in Section 9.3.7 or indirectly from the soil carbon percentage as described in Section 8.1.4.3.
Value applied	N/A

[23] Calculated from peak aboveground biomass data from 20 sites summarized in Mitsch & Gosselink. The median of these studies is 1.3 t d.m. ha^{-1}. This was converted to the default factor value as follows: 1.3 × 0.45 × 0.5 × 10. The factor 0.45 converts organic matter mass to carbon mass; the factor 0.5 is a factor that averages annual peak biomass (factor = 1) and annual minimum biomass (factor = 0, assuming ephemeral aboveground biomass and complete litter decomposition.

Justification of choice of data or description of measurement methods and procedures applied	The equations provided were developed for tidal marsh soils by Craft *et al*. 1991 and for mangrove soils by Allen 1974
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comments	N/A

Data / Parameter	$\%C_{soil}$
Data unit	%
Description	Percentage of soil organic C
Equations	33, 37, 39
Source of data	Direct measurements or may be derived from direct measurements of soil organic matter. These measurements may be made using samples collected in Section 9.3.7 or indirectly from the soil organic matter percentage determined through loss-on-ignition as described in Section 9.3.6.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	See Source of data above
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comments	N/A

Data / Parameter	*BD*
Data unit	kg m^{-3}
Description	Dry bulk density

Source of data	Direct measurements or, for the determination of allochthonous carbon, may be derived from soil carbon percentage as described in Section 8.1.4.3.
Value applied	N/A
Justification of choice of data or description of	Mass of soil material after drying to removed water per volume of soil material

measurement methods and procedures applied	
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comments	N/A

Data / Parameter	$\%OM_{depsed}$
Data unit	%
Description	Percentage of organic matter in deposited sediment
Equations	34, 38, 40
Source of data	May be estimated directly using loss-on-ignition (LOI) data, indirectly from soil carbon percentage as described in Section 8.1.4.3, or from the default value provided in Section 8.1.4.3. These measurements may be made using samples collected on sediment tiles or through collection and carbon analysis (see Section 9.3.7) of suspended sediments in tidal channels or sediments deposits in tidal flats.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	LOI may be assessed using standard laboratory procedures
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comments	N/A

Data / Parameter	$\%C_{depsed}$
Data unit	%
Description	Percentage of carbon in deposited sediment; %
Equations	38, 40
Source of data	May be estimated directly using loss-on-ignition (LOI) data or indirectly from soil carbon percentage as described in Section 8.1.4.3. These measurements may be made using samples collected on sediment tiles or through collection and carbon analysis (see

	Section 9.3.7) of suspended sediments in tidal channels or sediments deposits in tidal flats.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	The default factor is derived from the maximum value (conservative) provided by Andrews *et al.* 2011
Purpose of data	Calculation of baseline emissions Calculation of project emissions
Comments	N/A

Data / Parameter	$EF_{N2O,burn}$
Data unit	g N_2O / kg dry biomass
Description	Emission factor for N_2O emissions from vegetation burning
Equations	63
Source of data	The project proponent may use factors that have been determined for grassland vegetation. A suitable EF_{N2O} value is 0.21, from Table 2.5 of the 2006 IPCC Guidelines for National Greenhouse Inventories.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	Nitrous oxide emission factors for the combustion of herbaceous wetland vegetation are not currently available in scientific literature. However, these emissions are expected to be similar to those for grassland vegetation.
Purpose of data	Calculation of project emissions
Comments	N/A

Data / Parameter	$EF_{CH4,burn}$
Data unit	g CH_4 / kg dry biomass
Description	Emission factor for CH_4 emissions from vegetation burning
Equations	64
Source of data	The project proponent may use factors that have been determined for grassland vegetation. A suitable EF_{CH4} value is 2.3, from Table 2.5 of the 2006 IPCC Guidelines for National Greenhouse Inventories.
Value applied	N/A

Justification of choice of data or description of measurement methods and procedures applied	Methane emission factors for the combustion of herbaceous wetland vegetation are not currently available in scientific literature. However, these emissions are expected to be similar to those for grassland vegetation.
Purpose of data	Calculation of project emissions
Comments	N/A

Data / Parameter	*allowable_uncert*
Data unit	%
Description	Allowable uncertainty; 20 percent or 30 percent at a 90 percent or 95 percent confidence level, respectively
Equations	73
Source of data	N/A
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	N/A
Purpose of data	Calculation of net GHG emissions reductions
Comments	N/A

Data / Parameter	$V_{ex,ty,i,t}$
Data unit	m^3
Description	Volume of timber extracted from within stratum *i* (does not include slash left onsite) by species *j* and wood product class *ty* in year *t*
Equations	83
Source of data	Data representing common practice in harvesting
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	This volume does not include logging slash left onsite. The project proponent should also make sure that extracted volumes are gross volumes removed (ie, not already discounting for estimated wood waste). Assignment of volume extracted to wood product class(es), must be substantiated on the basis of participatory rural appraisal (PRA) findings or records of timber sales. Assignment of volume extracted to species, must be substantiated on the basis of either PRA findings, harvest records, or a commercial

	inventory.
Purpose of Data	Calculation of project emissions
Comments	N/A

Data / Parameter	D_j
Data unit	t d.m. m^{-3}
Description	Basic wood density in t d.m. m^{-3} for species *j*
Equations	83
Source of data	The source of data shall be chosen with priority from higher to lower preference as follows: (a) National species-specific or group of species-specific (eg, from National GHG inventory); (b) Species-specific or group of species-specific from neighboring countries with similar conditions. Sometimes (b) may be preferable to (a); (c) Global species-specific or group of species-specific (eg, IPCC 2006 INV GLs AFOLU Chapter 4 Tables 4.13 and 4.14). Species-specific wood densities may not always be available, and may be difficult to apply with certainty in the typically species rich forests of the humid tropics, hence it is acceptable practice to use wood densities developed for forest types or plant families or species groups.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	Where using wood densities developed outside of the project country (cases (b) and (c) above under Source of data), wood densities must be validated with either limited destructive sampling or direct measurement of wood hardness (eg, with a Pilodyn wood tester) in the field and correlating with wood density. Samples or measurements should be from 20-30 trees. For validation of mean forest type or species group wood densities, representation of species in the sample should be proportional to their occurrence in terms of basal area or volume in the project area (not abundance or stem density). Samples should provide representation across the length of the tree. Wood samples are cut in discs and thickness and diameter measured to calculate green volume. Samples are oven dried (105° C) to a constant weight in the laboratory, and density calculated as dry weight (g) per unit green volume (cm^3). If the density of the samples/measurements (or mean density in the

	case of forest type or species group means) is within ±10 percent of the selected density values, then the selected density values may be used. Otherwise, a new density value must be developed with more extensive sampling, using the validation samples as a base. Where new species are encountered in the course of monitoring, new wood density values must be sourced from the literature and validated, if necessary, as per requirements and procedures above.
Purpose of Data	Calculation of project emissions
Comments	N/A

Data / Parameter	CF_j
Data unit	t C t-1 d.m.
Description	Carbon fraction of dry matter in t C t^{-1} d.m. for species *j*
Equations	83
Source of data	Species- or family-specific values from the literature (eg, IPCC 2006 INV GLs AFOLU Chapter 4 Table 4.3) shall be used if available, otherwise default value of 0.47 t C t^{-1} d.m. can be used.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	N/A
Purpose of Data	Calculation of project emissions
Comments	N/A
Data / Parameter	WW_{ty}
Data unit	dimensionless
Description	Fraction of extracted biomass effectively emitted to the atmosphere during production by class of wood product *ty*
Equations	84
Source of data	The source of data is the published paper of Winjum *et al*. 1998[24]
Value applied	Winjum *et al*. 1998 indicate that the proportion of extracted biomass that is oxidized (burning or decaying) from the production of commodities to be equal to 19 percent for developed countries, 24 percent for developing countries. *WW* is therefore equal to $C_{XB,ty}$

[24] Winjum, J.K., Brown, S. and Schlamadinger, B. 1998. Forest harvests and wood products: sources and sinks of atmospheric carbon dioxide. *Forest Science* 44: 272-284

	multiplied by 0.19 for developed countries and 0.24 for developing countries.
Justification of choice of data or description of measurement methods and procedures applied	Parameter values to be updated if new empirically-based peer-reviewed findings become available.
Purpose of Data	Calculation of project emissions
Comments	N/A

Data / Parameter	SLF_{ty}
Data unit	Dimensionless
Description	Fraction of wood products that will be emitted to the atmosphere within 5 years of production by class of wood product *ty*
Equations	84
Source of data	The source of data is the published paper of Winjum *et al*. 1998[25]
Value applied	Winjum *et al.* 1998 give the following proportions for wood products with short-term (<5 yr) uses after which they are retired and oxidized (applicable internationally): Sawnwood 0.2 Woodbase panels 0.1 Other industrial roundwood 0.3 Paper and Paperboard 0.4 The methodology makes the assumption that all other classes of wood products, and where wood product class *ty* is unknown, are 100 percent oxidized within 5 years. Therefore SLF, by wood product class, is equal to: Wood Product Class – SLF Sawnwood – 0.2 Woodbase panels – 0.1 Other industrial roundwood – 0.3 Paper and paperboard – 0.4 Other classes of wood products – 1.0
Justification of choice of	Parameter values to be updated if new empirically-based peer-

[25] Winjum, J.K., Brown, S. and Schlamadinger, B. 1998. Forest harvests and wood products: sources and sinks of atmospheric carbon dioxide. *Forest Science* 44: 272-284

data or description of measurement methods and procedures applied	reviewed findings become available.
Purpose of Data	Calculation of project emissions
Comments	N/A

Data / Parameter	OF_{ty}
Data unit	Dimensionless
Description	OF = Fraction of wood products that will be emitted to the atmosphere between 5 and 100 years after production by class of wood product *ty*
Equations	84
Source of data	The source of data is the published paper of Winjum *et al*. 1998[26]
Value applied	Winjum *et al*. 1998 gives annual oxidation fractions for each class of wood products split by forest region (boreal, temperate and tropical). This methodology projects these fractions over 95 years to give the additional proportion (*OF* value) that is oxidized between the 5th and 100th years after initial harvest: <table><tr><th rowspan="2">Wood Product Class</th><th colspan="3">OF</th></tr><tr><th>Boreal</th><th>Temperate</th><th>Tropical</th></tr><tr><td>Sawnwood</td><td>0.36</td><td>0.60</td><td>0.84</td></tr><tr><td>Woodbase panels</td><td>0.60</td><td>0.84</td><td>0.97</td></tr><tr><td>Other industrial roundwood</td><td>0.84</td><td>0.97</td><td>0.99</td></tr><tr><td>Paper and paperboard</td><td>0.36</td><td>0.60</td><td>0.99</td></tr></table>
Justification of choice of data or description of measurement methods and procedures applied	Parameter values to be updated if new empirically-based peer-reviewed findings become available. Every 10 years, project proponents should review research findings to identify further refinements to the emission factors that are empirically-based and peer-reviewed.
Purpose of Data	Calculation of project emissions
Comments	N/A

[26] Winjum, J.K., Brown, S. and Schlamadinger, B. 1998. Forest harvests and wood products: sources and sinks of atmospheric carbon dioxide. *Forest Science* 44: 272-284

Data / Parameter	*BCEF*
Data unit	Dimensionless
Description	Biomass conversion and expansion factor for conversion of commercial wood volume per unit area to total aboveground tree biomass per unit area; note that BCEF as defined here, and in most applications, is not applied on a per stem basis
Equations	85
Source of data	Equations must have been derived using a wide range of measured variables (commercial wood volume per unit area and total aboveground biomass per unit area) based on datasets that comprise at least 30 trees. Equations must be based on statistically significant regressions and must have an r^2 that is ≥ 0.8. The source of data shall be chosen with priority from higher to lower preference as follows: (a) Existing local forest type-specific; (b) National forest type-specific or eco-region-specific (eg, from national GHG inventory); (c) Forest type-specific or eco-region-specific from neighboring countries with similar conditions. Sometimes (c) might be preferable to (b); (d) Global forest type or eco-region-specific (eg, IPCC 2006 INV GLs AFOLU Chapter 4 Table 4.5) The project volume data to which the selected BCEF is applied must conform to the data the BCEF was originally derived from, in particular, it must match forest type, stand structure, minimum DBH, and cover the range of potential independent variable values (commercial volumes) likely to be encountered in the project area. Care must be taken to ensure that the selected BCEF does not account for non-commercial species not represented in commercial volume estimates (ie, is restricted to expanding merchantable volumes to account for only non-merchantable tree components).
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	Alternatively, BCEF, where not directly available, can be calculated as wood density (t dry mass m^{-3} green volume) × BEF (Biomass Expansion Factor = ratio of aboveground biomass to biomass of the commercial volume). If using BCEFs developed outside the project country (cases (c) and (d) above under Source of data), it is necessary to validate the applicability of BCEFs used. Validation is performed by: 1. Limited Measurements

	Select at least 20 plots in the project area covering a wide range of commercial volumes. Obtain tree measurements (e.g. DBH, height to a 10 cm diameter top) from which to calculate commercial volume and total biomass. Calculate commercial volume per unit area (e.g. using Smalian's formula) and total biomass per unit area (using the biomass equation(s) selected for application in CP-AB) for each plot Calculate BCEF for each plot (biomass (t) / commercial volume (m^3) Graph the plot-level estimates of BCEF versus commercial volume along with the BCEF equation (predicted) to be validated. If the estimated BCEFs of the measured plots are distributed both above and below the predicted value the BCEF equation may be used. The BCEF equation may also be used if the measured plots have a BCEF consistently lower than that predicted. If graphing the BCEF of the measured plots indicates a systematic bias to overestimation of BCEF (>75 percent of the plots below the predicted value) then another BCEF equation must be selected or developed anew.
Purpose of Data	Calculation of project emissions
Comments	N/A

Data / Parameter	$Pcom_{i,t}$
Data unit	Dimensionless
Description	Commercial volume as a percent of total aboveground volume in stratum *i* in year *t*
Equations	85
Source of data	The source of data shall be chosen with priority from higher to lower preference as follows: (a) Direct forest inventory of the project area, distinguishing commercially viable stocks on the basis of species and tree size, referencing local expert knowledge or a participatory rural assessment (PRA) of harvest practices and markets; (b) Forest inventory from a proxy area in the same region, representing the same forest type and age class, distinguishing commercially viable stocks on the basis of species and tree size, referencing local expert knowledge of harvest practices and markets National and forest type-specific or eco-region-specific (eg, from National GHG inventory).

Purpose of data	Calculation of project emissions
Calculation method	N/A
Comments	N/A

Data / Parameter	$Rate_{subs-WPS,i}$
Data unit	m yr^{-1}
Description	Rate of organic soil loss due to subsidence in the project scenario in stratum *i*
Equations	Similar to 28
Source of data	The rate of organic soil loss due to subsidence must be based on verifiable information and may be derived from: 1) Data must be based on surface height measurements relative to a fixed reference point in m asl, following methods described in Ballhorn *et al*. 2009 (eg, using poles fixed in the underlying mineral soil or rock, or by remote sensing) or similar. Or 2) CO_2 emissions derived from GHG emission proxies, see Section 8.1.4.2.1 above, in combination with data on volumetric carbon content of the organic soil. Divide the annual CO_2 emission (t CO_2 ha^{-1}) by 44/12, then divide by volumetric carbon content (g C cm^{-3}) to obtain height loss in m. The average depth of burn scars may be derived from expert judgment, datasets and/or literature of historic burn depths involving the project or similar areas. Data must be based on surface height measurements, using field measurements or remote sensing (eg, following methods described in Ballhorn *et al*. 2009). The areal extent of burn scars may be obtained from statistics and/or maps in official reports and/or field measurements

	or remote sensing data.
Justification of choice of data or description of measurement methods and procedures applied	See *Source of data* above and Couwenberg & Hooijer (2013).
QA/QC procedures to be applied	See Section 9.3.2
Purpose of data	Calculation of project emissions
Calculation method	See Source of data above
Comments	Refer to procedures set out in Sections 8.1.4.2.1 – 8.1.4.2.6. For all equations in these sections, the subscript *BSL* must be substituted by *WPS* to make clear that the relevant values are being quantified for the project scenario.

Data / Parameter	$C_{WPS\text{-}soil,i,t}$
Data unit	t C ha^{-1}
Description	Soil organic carbon stock in the project scenario in stratum *i* in year *t*
Equations	Similar to 29
Source of data	Soil coring may be used to generate a value of $C_{WPS\text{-}soil,i,t}$ *as* specified in Section 9.3.7
Justification of choice of data or description of measurement methods and procedures applied	Specified in Section 9.3.7
Purpose of data	Calculation of project emissions
Comments	Refer to procedures set out in Sections 8.1.4.2.1 – 8.1.4.2.6. For all equations in these sections, the subscript *BSL* must be substituted by *WPS* to make clear that the relevant values are being quantified for the project scenario.

Data / Parameter	$\%OM$ (or $\%OM_{soil}$)
Data unit	%
Description	Percentage of soil organic matter
Equations	34, 35, 37, 39, 76, 77, 79, 79

Source of data	Direct measurements based on loss-on-ignition or may be derived from direct measurements of soil carbon. These measurements may be made using samples collected in Section 9.3.7 or indirectly from the soil carbon percentage as described in Section 8.1.4.3.
Description of measurement methods and procedures to be applied	The equations provided were developed for tidal marsh soils by Craft *et al*. 1991 and for mangrove soils by Allen 1974

	substituted by *WPS* to make clear that the relevant values are being quantified for the project scenario.

Data / Parameter	*BD*
Data unit	kg m^{-3}
Description	Dry bulk density
Equations	80
Source of data	Direct measurements or, for the determination of allochthonous carbon, may be derived from soil carbon percentage as described in Section 8.1.4.3.
Description of measurement methods and procedures to be applied	Mass of soil material after drying to removed water per volume of soil material
QA/QC procedures to be applied	See Section 9.3.2
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comments	Refer to procedures set out in Sections 8.1.4.2.1 – 8.1.4.2.6. For all equations in these sections, the subscript *BSL* must be substituted by *WPS* to make clear that the relevant values are being quantified for the project scenario.

Data / Parameter	$\%OM_{depsed}$
Data unit	%
Description	Percentage of organic matter in deposited sediment
Equations	34, 38, 40
Source of data	May be estimated directly using loss-on-ignition (LOI) data, indirectly from soil carbon percentage as described in Section 8.1.4.3, or from the default value provided in Section 8.1.4.3. These measurements may be made using samples collected on sediment tiles or through collection and carbon analysis (see Section 9.3.7) of suspended sediments in tidal channels or sediments deposits in tidal flats
Description of measurement methods	LOI may be assessed using standard laboratory procedures

and procedures to be applied	
QA/QC procedures to be applied	See Section 9.3.2
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comments	Refer to procedures set out in Sections 8.1.4.2.1 – 8.1.4.2.6. For all equations in these sections, the subscript *BSL* must be substituted by *WPS* to make clear that the relevant values are being quantified for the project scenario.

Data / Parameter	$\%C_{depsed}$
Data unit	%
Description	Percentage of carbon in deposited sediment; %
Equations	38, 40
Source of data	May be estimated directly using loss-on-ignition (LOI) data or indirectly from soil carbon percentage as described in Section 8.1.4.3. These measurements may be made using samples collected on sediment tiles or through collection and carbon analysis (see Section 9.3.7) of suspended sediments in tidal channels or sediments deposits in tidal flats.
Description of measurement methods and procedures to be applied	The default factor is derived from the maximum value (conservative) provided by Andrews *et al.* 2011
QA/QC procedures to be applied	See Section 9.3.2
Purpose of data	Calculation of project emissions
Calculation method	N/A
Comments	Refer to procedures set out in Sections 8.1.4.2.1 – 8.1.4.2.6. For all equations in these sections, the subscript *BSL* must be substituted by *WPS* to make clear that the relevant values are being quantified for the project scenario.

Data Unit / Parameter	$ET_{FC,y}$

Data unit	t CO_2-e yr^{-1}
Description	CO_2 emissions from fossil fuel combustion during the year *y*; t CO_2 yr^{-1}
Equations	65
Source of data	Derived from application of CDM tool Estimation of GHG emissions related to fossil fuel combustion in A/R CDM project activities
Description of measurement methods and procedures to be applied	See *AR-Tool14*
Frequency of monitoring/recording	See the *AR Tool*
QA/QC procedures to be applied	See the *AR Tool*
Purpose of data	Calculation of project emissions
Calculation method	See the *AR Tool*
Comments	Calculations are done for each stratum *i*

Data / Parameter	NER_{ERROR}
Data unit	%
Description	Total uncertainty for project activity
Equations	72, 73
Source of data	*N/A*
Description of measurement methods and procedures to be applied	N/A
QA/QC procedures to be applied	N/A
Purpose of data	Calculation of net GHG emission reductions
Calculation method	N/A
Comments	N/A

Data / Parameter	$V_{ex,ty,i,t}$
Data unit	m^3

Description	Volume of timber extracted from within stratum *i* (does not include slash left onsite) by species *j* and wood product class *ty* in year *t*
Equations	83
Source of data	Estimates derived from field measurements or remote assessments with aerial photography or satellite imagery.
Justification of choice of data or description of measurement methods and procedures applied	See Section 9.1
QA/QC procedures to be applied	
Purpose of Data	Calculation of project emissions
Comments	N/A

9.3 Description of the Monitoring Plan

9.3.1 General

The main objective of project monitoring is to reliably quantify carbon stocks and GHG emissions in the project scenario during the project crediting period, prior to each verification, with the following main tasks:

- Monitor project carbon stock changes and GHG emissions
- Estimate *ex-post* net carbon stock changes and GHG emissions, and GHG emission reductions

The monitoring plan must contain at least the following information:

- A description of each monitoring task to be undertaken, and the technical requirements therein
- Parameters to be measured
- Data to be collected and data collection techniques
- Frequency of monitoring
- Quality assurance and quality control (QA/QC) procedures
- Data archiving procedures
- Roles, responsibilities and capacity of monitoring team and management

9.3.2 Uncertainty and quality management

Quality management procedures are required for the management of data and information, including the assessment of uncertainty relevant to the project and baseline scenarios. As far as practical, uncertainties related to the quantification of GHG emission reductions and removals by sinks should be reduced.

To help reduce uncertainties in the accounting of emissions and removals, this methodology uses whenever possible the methods from the GPG-LULUCF, GPG-2000, the IPCC's Revised 2006 Guidelines and peer-reviewed literature. Despite this, potential uncertainties still arise from the choice of parameters to be used. Uncertainties arising from input parameters would result in uncertainties in the estimation of both baseline net GHG emissions and project net GHG emissions, especially when global default factors are used. The project proponent must identify key parameters that would significantly influence the accuracy of estimates. Local values that are specific to the project circumstances must then be obtained for these key parameters, whenever possible. These values should be based on:

- Data from well-referenced peer-reviewed literature or other well-established published sources[27];
- National inventory data or default data from IPCC literature that has, whenever possible and necessary, been checked for consistency against available local data specific to the project circumstances; or
- In the absence of the above sources of information, expert opinion may be used to assist with data selection. Experts will often provide a range of data, as well as a most probable value for the data. The rationale for selecting a particular data value must be described in the project description.

In choosing key parameters, or making important assumptions based on information that is not specific to the project circumstances, such as in use of default data, the project proponent must select values that will lead to an accurate estimation of net GHG emission reductions, taking into account uncertainties.

If uncertainty is significant, the project proponent must choose data such that it indisputably tends to under-estimate, rather than over-estimate, net GHG project benefits.

To ensure that carbon stocks are estimated in a way that is accurate, verifiable, transparent, and consistent across measurement periods, the project proponent must establish and document clear standard operating procedures and procedures for ensuring data quality. At a minimum, these procedures must include:

- Comprehensive documentation of all field measurements carried out in the project area.

[27] Typically, citations for sources of data used should include: the report or paper title, publisher, page numbers, publication date, etc. (or a detailed web address). If web-based reports are cited, hardcopies should be included as annexes in the project description if there is any likelihood that such reports may not be permanently available.

This document must be detailed enough to allow replication of sampling in the event of staff turnover between monitoring periods.

- Training procedures for all persons involved in field measurement or data analysis. The scope and date of all training must be documented.
- A protocol for assessing the accuracy of plot measurements using a check cruise and a plan for correcting the inventory if errors are discovered.
- Protocols for assessing data for outliers, transcription errors, and consistency across measurement periods.
- Data sheets must be safely archived for the life of the project. Data stored in electronic formats must be backed up.

9.3.3 Expert judgment

The use of expert judgment for the selection and interpretation of methods, selection of input data to fill gaps in available data, and selection of data from a range of possible values or uncertainty ranges, is well established in the IPCC 2006 good practice guidance. Obtaining well-informed judgments from domain experts regarding best estimates and uncertainties is an important aspect in various procedures throughout this methodology. The project proponent must use the guidance provided in Chapter 2 (Approaches to Data Collection), in particular, Section 2.2 and Annex 2A.1 of the IPCC 2006 good practice guidance.

9.3.4 Monitoring of project implementation

Information must be provided and recorded in the project description to establish that:

1) The geographic position of the project area is recorded for all areas of wetland. The geographic coordinates of the project area (and any stratification or buffer zones inside the area are established, recorded and archived. This can be achieved by field survey (eg, using GPS), or by using georeferenced spatial data (eg, maps, GIS datasets, orthorectified aerial photography or georeferenced remote sensing images). The above also applies to the recording of strata.
2) Commonly accepted principles of land use inventory and management are implemented.
    - Standard operating procedures (SOPs) and quality control/quality assurance (QA/QC) procedures for inventories including field data collection and data management must be applied. Use or adaptation of SOPs already applied in national land use monitoring, or available from published handbooks, or from the IPCC GPG LULUCF 2003, is recommended.
    - Apply SOPs, especially, for actions likely to cause soil disturbances.
    - Project planning documentation, together with a record of the plan as actually implemented during the project must be available for validation or verification, as appropriate.

Continued compliance with the applicability conditions of this methodology must be ensured by monitoring that:

- The water table is not lowered except where the project converts open water to tidal wetlands, or improves the hydrological connection to impounded waters.
- The burning of organic soil as a project activity does not occur.
- Peatland fires within the project area do not occur in the project scenario. If they do occur as non-catastrophic events, they are accounted for by cancelling the *Fire Reduction Premium* for the entire project or the individual project activity instance.
- N-fertilizers are not used within the project area in the project scenario.

Where the project proponent chooses to monitor alterations of water table depth in the project area to demonstrate no alteration of mean annual water table depths in adjacent areas, or that such alteration is limited to levels that do not influence GHG emissions, the project proponent must use water level gauges or vegetation assessments, or a combination of these. Water level gauges must be installed in the project area and readings must be compared with the hydrological modeling results or expert judgment on which the establishment of the project area was based. The number and spacing of water level gauges must be based on hydrological modeling or expert judgment.

9.3.5 Stratification and sampling framework

Stratification of the project area into relatively homogeneous units may either increase the measuring precision without increasing the cost unduly, or reduce the cost without reducing measuring precision because of the lower variance within each homogeneous unit. The project proponent must present in the project description an *ex-ante* stratification of the project area or justify the lack of it. The number and boundaries of the strata defined *ex ante* may change during the project crediting period (*ex post*).

The *ex-post* stratification must be updated where the following occur:

- Unexpected disturbances occurring during the project crediting period (eg, due to changes in the hydrology, fire, pests or disease outbreaks), affecting differently various parts of an originally homogeneous stratum;
- Management activities (forestry, agriculture, hydrology) that are implemented in a way that affects the existing stratification.

Established strata may be merged if the reasons for their establishment are no longer relevant.

The sampling framework, including sample size, plot size, plot shape, and determination of plot location must be specified in the project description. Where changes in carbon stocks are to be monitored (eg, in trees), permanent sampling plots must be used, noting the following:

1) To determine the sample size and allocation among strata, the latest version of the CDM tool *Calculation of the number of sample plots for measurements within A/R CDM project activities* may be used. The targeted confidence interval must be 90 percent or 95 percent. Where a 90 percent confidence interval is adopted and the width of the confidence interval exceeds 20 percent of the estimated value or where a 95 percent confidence interval is adopted and the width of the confidence interval exceeds 30 percent of the estimated value, an appropriate confidence deduction must be applied, as specified in Section 8.5.2.
2) In order to avoid bias, sample plots should be marked inconspicuously.
3) The sample plot size must be established according to common practice in forest, vegetation and soil inventories.
4) To avoid subjective choice of plot locations, the permanent sample plots must be located either systematically with a random start or completely randomly inside each defined stratum. The geographical position (GPS coordinate), administrative location, stratum and stand, series number of each plot, as well as the procedure used for locating them must be recorded and archived. The sampling plots are to be as evenly distributed as possible, where larger strata have more plots than smaller strata. However, remote areas and areas with poor accessibility may be excluded for the location of sampling plots. Such areas must be mapped as separate strata and for these strata accounting of carbon stocks in tree biomass in the project scenario is conservatively omitted (see Section 8.2.2).

The choice of monitoring frequency must be justified in the project description.

9.3.6 Sampling of herbaceous vegetation

Aboveground herbaceous mass (herb) is defined as a pool that includes both living plant mass (ie, biomass) and dead plant mass (ie, litter). All living and dead herbaceous mass is clipped above the soil surface from inside each sample frame. Dry mass is determined by either drying the entire wet sample to a constant weight, or drying a subsample of the wet mass to determine a dry-to-wet mass ratio conversion factor. Because aboveground mass can be highly seasonal, the average pool must be calculated from at least two samples representing the minimum and maximum standing stocks. Alternatively, a conservative estimate of the pool may be determined from a sample taken at the time of minimum standing stock.

9.3.7 Soil coring approach for estimating soil carbon

Soil organic carbon may be estimated by determining the organic carbon accumulated above a consistent reference plane and then dividing by the years since the date of the reference plane (for the baseline scenario) or the start of project activities (for the project scenario). The reference plane must be established using a marker horizon (most commonly using feldspar)[28], a strongly contrasting soil layer (such as the boundary between organic and mineral soil materials), an

[28] Cahoon & Turner 1989

installed reference plane (such as the shallow marker in a surface elevation table)[29], a layer identified biogeochemically (such as through radionuclide, heavy metal, or biological tracers)[30], a layer with soil organic carbon indistinguishable from the baseline SOC concentration (as determined in Section 8.1.4.2)[31] or other accepted technologies. Note that feldspar marker horizons should not be used in systems where they are unstable, such as some sandy soils and systems with significant bioturbation. The material below the reference plane may be conservatively assumed to have zero change due to project activities.

The material located above the reference plane must be analyzed for total carbon and bulk density. Sediment samples may be collected for the estimation of $\%C_{depsed}$ (see Section 8.1.4.3) using sediment tiles,[32] through collection of suspended sediments in tidal channels during a period of high suspended sediment concentration or by collecting cores of sediment deposits in tidal flats. Total organic carbon must be analyzed directly using CHN elemental analysis or the Walkley-Black chromic acid wet oxidation method or determined from loss-on-ignition (LOI) data using the following equation:

$\%C = 0.04 \times \%OM + 0.0025 \times \%OM^2$ (only for marsh soils)[33] **(76)**

$\%C = \%OM / 1.724$ (only for mangrove soils)[34] **(77)**

$\%C = -0.21 + 0.40\ (\%OM)$ (only for seagrass soils with $\%OM < 20$ percent) [35] **(78)**

$\%C = -0.33 + 0.43\ (\%OM)$ (only for seagrass soils with $\%OM > 20$ percent) [36] **(79)**

Alternatively, an equation developed using site-specific data may be used or an equation from peer-reviewed literature may be used if the equation represents soils from the same or similar systems as those in the project area.

Inorganic carbon should be removed from samples if present in significant quantities, usually through acid treatment (such as sulfurous or hydrochloric acid). Live coarse below-ground tree biomass should be removed from soil samples prior to analysis. Additional live below-ground biomass may be removed or included. Soil samples collected may be aggregated to reduce the variability.

The mass of carbon per unit area is calculated as follows:

[35] Fourqurean *et al*. 2012 as summarized in Howard *et al*. 2014
[36] Fourqurean *et al*. 2012 as summarized in Howard *et al*. 2014

$$C_{WP,SOCacc} = 44/12 \times \sum_{i=1}^{Ndepth} \left(CF_{SOC,sample} \times BD \times Thickness \times 100 \right) \quad \textbf{(80)}$$

Where:

$C_{WP,SOCacc}$	Average accumulation of soil/sediment over reference plane in the project; t CO_2e ha^{-1}
44/12	Ratio of molecular weight of CO_2 to carbon; dimensionless
Ndepth	Number for soil horizons, based on subdivisions of soil cores
CF_{SOC_sample}	Carbon fraction of the sample, as determined in laboratory; %
BD	Bulk density, as determined in laboratory; g cm^{-3}
Thickness	Thickness of soil horizon; cm
100	Conversion factor of g cm^{-3} to Mg ha^{-1}

9.3.8 Monitoring CH_4 and N_2O emissions

Direct measurement of CH_4 and/or N_2O emissions may be made with either a closed chamber technique or a chamber-less technique such as eddy covariance flux. For eddy covariance methods, the guidelines presented in VCS methodology *VM0024 Methodology for Coastal Wetland Creation* must be followed, taking into account the additional guidance below.

Flux measurements are expected to conform to standard best practices used in the scientific community[37]. The basic design of the closed chamber for wetlands requires a base that extends into the soil (5 cm minimum), and a chamber that is placed over the plants and sealed to the base. To prevent the measurement from disturbing CH_4 emissions, the base should be placed at least one day in advance, and the plot should be approached on an elevated ramp or boardwalk when taking samples, although failure to do so is conservative because it will cause higher fluxes. CH_4 flux is calculated as the difference in initial and final headspace CH_4 concentration, without removing non-linear increases caused by bubble (ebullition) fluxes that may have occurred. Initial and final concentrations will be determined as the average of duplicate determinations. Because CH_4 and N_2O emissions can be low from tidal wetlands, it may be necessary to enclose large areas (≥ 0.25 m^2) or lengthen the measurement period to improve sensitivity.

Methane emissions from strata lacking vegetation (<25 percent cover), such as open water, hollows or ponds, can be dominated by episodic bubble emissions (ie, ebullition). Chambers for open water emissions are typically a single piece that floats such that the bottom extends under the water surface (5 cm minimum). Floating chambers must be deployed for a minimum of 4 days.

Eddy covariance techniques sense total CH_4 and N_2O emissions (diffusive and ebullition) at high temporal resolution; such systems must be deployed for a minimum of 48 hours of useable data.

---

[37] *Oremland 1975*

CH_4 and N_2O emission estimates must be either accurate or conservative. Accurate estimates must account for variation in time caused by changes in plant activity, temperature, water table depth, salinity and other sources of variation, and in space caused by factors such as topography (eg, hummocks versus hollows) or plant cover. A conservative estimate may be based on direct measurements taken at times and places in which CH_4 or N_2O emissions are expected to be the highest based on expert judgment, datasets or literature.

Fluxes must be measured in the stratum with the highest emissions. For CH_4, these are likely to be strata in the wettest strata that support emergent vegetation, but may include stagnant pools of water. Eddy flux towers must be placed so that the footprint lies in the stratum with the highest CH_4 or N_2O emissions for 50 percent of the time. CH_4 fluxes must be measured when the water table is <10 cm from the soil surface, during times of year when emissions are highest, such as the warmest month and/or wettest month. When CH_4 emission rates incorporate measurements from periods of time outside the peak, they must be made at approximately monthly intervals.

In addition to the conservative principles above, the project proponent must consider other factors that are specific to the method applied. In particular, closed chambers must be transparent and deployed in daylight unless it is can be shown that CH_4 emissions are not sensitive to light.

Regardless of method, emissions must be averaged and expressed as daily (24 hour) rates and converted to annual estimates using the following equations:

$$GHG_{WPS\text{-}soil\text{-}CH4,i,t} = GHG_{CH4\text{-}daily,i,t} \times 365 \times CH_4\text{-}GWP \quad \textbf{(81)}$$

Where:

$GHG_{WPS\text{-}soil\text{-}CH4,i,t}$	CH_4 emissions from the SOC pool in the project scenario in stratum *i* in year *t*; t CO_2e ha^{-1} yr^{-1}
$GHG_{CH4\text{-}daily,i,t}$	Average daily CH_4 emissions in the baseline scenario based on direct measurements of stratum *i* in year *t*; mg CH_4 m^{-2} d^{-1}
$CH_4\text{-}GWP$	Global warming potential of CH_4; dimensionless
i	1, 2, 3 …M_{WPS} strata in the baseline scenario
t	1, 2, 3, … *t** years elapsed since the project start date

$$GHG_{WPS\text{-}soil\text{-}N2O,i,t} = GHG_{N2O\text{-}daily,i,t} \times 365 \times N2O\text{-}GWP \quad \textbf{(82)}$$

Where:

$GHG_{WPS\text{-}soil\text{-}N2O,i,t}$	N_2O emissions from the SOC pool in the project scenario in stratum *i* in year *t*; t CO_2e ha^{-1} yr^{-1}
$GHG_{N2O\text{-}daily,i,t}$	Average daily N_2O emissions in the baseline scenario based on direct measurements of stratum *i* in year *t*; mg N_2O m^{-2} d^{-1}
$N_2O\text{-}GWP$	Global warming potential of N_2O; dimensionless
i	1, 2, 3 …M_{WPS} strata in the baseline scenario

t 1, 2, 3, … *t** years elapsed since the project start date

Where the default factor approach is used for CH_4 emissions (see Section 8.1.4.4.4), the salinity average or salinity low point will be measured on shallow pore water (within 30 cm from soil surface) using a handheld salinity refractometer or other accepted technology. The salinity average must be calculated from observations that represent variation in salinity during periods of peak CH_4 emissions (eg, during the growing season in temperate ecosystems or the wet season in tropical ecosystems). When the number of observations during this period is small (fewer than one per month for one year), the salinity low point from these data must be used. The salinity of the floodwater source (eg, an adjacent tidal creek) during this period may be used as a proxy for salinity in pore water provided there is regular hydrologic exchange between the source and the wetland (ie, the source floods the wetland at least on 20 percent of high tides).

9.3.9 Monitoring of soil subsidence

Where soil subsidence on drained wetlands is used as a proxy for carbon loss and CO_2 emissions, applied techniques and calculations must follow international standards of application or local standards as laid out in pertinent scientific literature or handbooks. The lowering of the organic soil surface over time (subsidence) must be measured relative to a fixed point (datum) (eg, using a pole fixed in the mineral subsoil). Dipwells used for water table depth monitoring may be used for subsidence monitoring with the advantage that water table depth and subsidence are monitored at the exact same location. In areas where fire may occur, it is best (also) to place iron poles. If poles are lost due to fire, new poles must be installed. Height losses due to fire must be treated separately from those caused by microbial oxidation of the organic soil in assessing carbon losses.

Interpolation of the trend in organic soil height loss over a longer period surrounding the fire event allows for quantifying height loss due to the fire. At least 10 replicate subsidence poles must be evenly distributed per stratum. To prevent disturbance, poles may need to be fenced in. In order to avoid disturbance of the organic soil surface during readings it is advisable to place boardwalks. For remote and inaccessible areas, the project proponent may rely on vegetation cover as an indicator for water table depth and associated subsidence rates as supported by data or literature references in a conservative way. The minimum monitoring frequency for soil subsidence is once a year.

Consolidation of the saturated organic soil below the water table may contribute to subsidence over multiple years. The project proponent must conservatively assess the contribution of consolidation to overall subsidence by reference to literature values or expert judgment or demonstrate that consolidation plays an insignificant role in overall subsidence (< 5 percent).

The calculation of carbon loss rates from subsidence data must follow pertinent scientific literature (eg, Couwenberg & Hooijer 2013) and usually requires data on the volumetric carbon content of the organic soil. When subsidence measurements are used to establish emission factors to be associated with other proxies, measurements must be carried out over a period of at least 24 months to cover intra- and inter-annual variability.

APPENDIX 1: LONG-TERM CARBON STORAGE IN WOOD PRODUCTS

Introduction

The procedures included in this appendix allow for the *ex-ante* estimation of carbon stocks in the long-term wood products pool in the project scenario. The procedures are applicable to all cases where wood is harvested for conversion to wood products for commercial markets, for all forest types and age classes.

The approach outlined employs an emission factor (*WW*) derived by Winjum *et al.* 1998. In the event that new research findings updating or refining (eg, for specific countries) the WW factor become available in the future (during the project crediting period), they must be used in place of the factors included in this appendix; otherwise the factors will remain valid. The use of this appendix requires that project proponents review research findings (that produce emissions factors compatible with the conceptual framework here) at least every 10 years to identify further refinements to the emission factors that are empirically based and peer reviewed.

All factors are derived from Winjum *et al*. 1998.

If approved timber harvest plans, specifying harvest intensity per strata in terms of volume extracted per ha, are available for the project area, use Option 1. If approved harvest plans are not available, use Option 2.

Once actual extraction data is obtained from the project site, they must be monitored and used for calculations. At each verification event, the long-term average must be recalculated based on past harvested volumes and most recent forecasts.

Option 1: Direct Volume Extraction Estimation

Step 1: Identify the wood product class(es) (*ty*; defined here as sawnwood, wood-based panels, other industrial roundwood, paper and paper board, and other) that are the anticipated end use of the extracted carbon calculated in Step 2.

Step 2: Calculate the biomass carbon of the volume extracted by wood product type *ty* from within the project boundary:

$$C_{XB,ty,i,t} = \sum_{j=1}^{S}(V_{ex,ty,j,i} \times D_j \times CF_j \times \frac{44}{12}) \qquad (\mathbf{83})$$

Where:

$C_{XB,ty,i}$	Extracted biomass carbon by class of wood product *ty* from stratum *i* in year *t*; t CO_2e
$V_{ex,ty,i,t}$	Volume of timber extracted from within stratum *i* (does not include slash left onsite) by species *j* and wood product class *ty* in year *t*; m^3
D_j	Mean wood density of species *j*; t d.m.m^{-3}
CF_j	Carbon fraction of biomass for tree species *j*; t C t^{-1} d.m.

j	1, 2, 3, … S tree species
ty	Wood product class – defined here as sawnwood (s), wood-based panels (w), other industrial roundwood (oir), paper and paper board (p), and other (o)
i	1, 2, 3 …*M* strata
t	1, 2, 3, … *t** years elapsed since the project start date
44/12	Ratio of molecular weight of CO_2 to carbon, t CO_2e t C^{-1}

Step 3: Calculate the proportion of biomass carbon extracted that remains sequestered in long-term wood products.

$$C_{WP,i,t} = \sum_{ty=s,w,oir,p,o} C_{XB,ty,i} \times (1 - WW_{ty}) \times (1 - SLF_{ty}) \times (1 - OF_{ty}) \quad \textbf{(84)}$$

Where:

$C_{WP,i,t}$	Extracted carbon in the wood products pool from stratum *i* in year *t*; t CO_2e
$C_{XB,ty,i,t}$	Mean stock of extracted biomass carbon by class of wood product *ty* from stratum *i*; in year *t* t CO_2e
WW_{ty}	Wood waste. The fraction immediately emitted through mill inefficiency by class of wood product *ty*; dimensionless
SLF_{ty}	Fraction of wood products that will be emitted to the atmosphere within 5 years of timber harvest by class of wood product *ty*; dimensionless
OF_{ty}	Fraction of wood products that will be emitted to the atmosphere between 5 and 100 years of timber harvest by class of wood product *ty*; dimensionless
ty	Wood product class – defined here as sawnwood (s), wood-based panels (w), other industrial roundwood (oir), paper and paper board (p), and other (o)
i	1, 2, 3, … *M* strata
t	1, 2, 3, … *t** years elapsed since the project start date

Option 2: Commercial Inventory Estimation

Step 1: Calculate the biomass carbon of the commercial volume extracted prior to or in the process of harvesting:

$$C_{XB,i,t} = C_{AB\_tree,i,t} \times \frac{1}{BCEF} \times Pcom_{i,t} \quad \textbf{(85)}$$

Where:

$C_{XB,i,t}$	Extracted biomass carbon from stratum *i* in year *t*; t CO_2e
$C_{AB\_tree,i,t}$	Aboveground biomass carbon stock in stratum *i* in year *t*; t CO_2e
BCEF	Biomass conversion and expansion factor (BCEF) for conversion of merchantable

	volume to total aboveground tree biomass; dimensionless
$Pcom_{i,t}$	Commercial volume as a percent of total aboveground volume in stratum *i*; dimensionless
i	1, 2, 3, … *M* strata
t	1, 2, 3, … *t** years elapsed since the project start date

Step 2: Identify the wood product class(es) (*ty*; defined here as sawnwood, wood-based panels, other industrial roundwood, paper and paper board, and other) that are the anticipated end use of the extracted carbon calculated in Step 1.

Step 3: Same as Step 3 in Option 1 above.

Data and parameters available at validation are provided in Section 9.1.

Data and parameters monitored are provided in Section 9.2.

APPENDIX 2: ACTIVITY METHOD

Introduction and Approach

Tidal wetland restoration activities in the United States are at a low level of penetration relative to their maximum adoption potential. Specifically, the activity penetration level of such activities is 2.74 percent (or lower), as demonstrated below. This level is below the 5 percent threshold specified in the *VCS Standard*. Therefore, tidal wetland restoration projects meeting the applicability conditions of this methodology and occurring within the 35 coastal states, commonwealths or territories of the United States of America are deemed additional.

Activity penetration is given as:

$$APy = OAy / MAPy$$

Where:

APy Activity penetration of the project activity in year y (percentage)

OAy Observed adoption of the project activity in year y

MAPy Maximum adoption potential of the project activity in year y

In determining the activity penetration for tidal wetlands, it is necessary to address seagrass meadows and other tidal wetlands separately due to how these ecosystems are treated in the data sources.

For tidal wetland restoration (excluding seagrass meadows) in the United States, these terms are further defined as follows:

OAy The average annual aggregate of tidal wetlands restored from 2000 to 2013 as reported by the 28 National Estuary Programs (NEPs) and their partners to the U.S. Environmental Protection Agency (measured in acreage), and expanded to include restoration activities that occur in a U.S. estuary that is not an NEP.

MAPy The sum of the following:

- A portion of the 1991 100-year Coastal Floodplain as determined by the Federal Emergency Management Agency (FEMA)
- Past tidal wetland losses to shallow open water in Louisiana due to coastal erosion
- Tidal wetland losses reported by the U.S. Fish and Wildlife Service (USFWS) from 1991 to 2013

For seagrass meadow restoration in the United States, these terms are defined as follows:

OAy The percentage of seagrass meadow restoration projects compared to other estuary restoration projects funded by NOAA since 2000.

MAPy The estimated acreage of seagrass meadow losses in the U.S.

Justification for Tidal Wetland Restoration Penetration Levels (Non-Seagrass)

The United States is a developed country where states have equal access to the nation's resources. Factors causing degradation are substantially the same throughout the United States. Climate is not a factor in degradation of tidal wetlands, which occur across all climatic regions in the United States.

No complete national data sets exist for either tidal wetland loss or restoration in the United States. However, for both *MAPy* and *OAy*, conservative approximations can be made by examining the data from several sources.

Time Period

The time period selected for determining the *OAy* is 2000 to 2013. This is an appropriate time period for the following reasons:

- The NEPs began reporting annual activities in 2000 and have been required to do so since 1993 by the Government Performance Results Act. The NEP database captures activities prior to 2000 as well as those from 2000 forward.
- The Estuary Restoration Act[38] was signed into law in 2000. The Act made restoring estuaries a national priority and represents a recognition of the growing importance of estuary habitat restoration, including tidal wetlands. It provided funding authorization and appropriations for restoration projects, and created a federal interagency council to promote a coordinated Federal approach to estuary habitat restoration; forge effective partnerships among public agencies and between the public and private sectors; provide financial and technical assistance for estuary habitat restoration projects; and, develop and enhance monitoring and research capabilities. Prior to 2000, the lack of interagency coordination created sporadic and uncoordinated restoration actions.
- NOAA's Community-based Restoration Program was created in 1999 within its Restoration Center and began funding projects that year with just $500,000 in funding[39]. The creation of this national center for restoration also indicates that a turning point for restoration was anticipated at that time. Since then, NOAA's annual funding for restoration has grown to well over 10 million dollars.
- Restore America' Estuaries (RAE) was established in 1997 as a national umbrella organization for regional non-profit organizations. These organizations identified estuary restoration as an emerging opportunity and established RAE to promote estuary restoration at the national level and to provide financial support for new restoration activities. The creation of RAE at this time reflects the need for a national voice to catalyze increased investment in estuary restoration.

[38] http://www.era.noaa.gov/information/act.html

[39] Personal communication in 2000 with the Restoration Center Director, James Burgess.

Collectively these milestones represented a sea change in the restoration community that has greatly increased funding and capacity for restoration activities since the year 2000, and therefore the time period 2000 to 2013 will capture the preponderance of restoration activities.

Activity Penetration

The 28 National Estuary Programs are an appropriate means to quantify restoration activity. The National Estuary Program (NEP) was established under Section 320 of the 1987 Clean Water Act as a U.S. Environmental Protection Agency program to protect and restore the water quality and ecological integrity of estuaries of national significance. The NEP consists of 28 individual estuary programs in the United States. Each NEP has a Management Conference consisting of diverse stakeholders including citizens, local, state and federal agencies, as well as non-profit and private sector interests. They emphasize a collaborative approach to establishing and implementing locally-based Comprehensive Conservation and Management Plans (CCMP).

The 28 estuaries with NEPs are the most advanced in conservation planning and implementation, including ecological restoration, and as such will have the greatest activity penetration levels of estuaries in the United States. They are also among the largest and most populated estuary regions in the U.S. Estuaries not included in the NEP will typically have a much lower penetration level for tidal wetland restoration.

That estuaries in NEPs face the same or similar barriers to implementation of tidal wetland restoration projects as estuaries that do not have an NEP is supported by the expert opinions supporting this document. The experts also confirm that the levels of restoration in NEPs are much greater than the levels of restoration occurring in non-NEP estuaries in the United States.

To undertake tidal wetland restoration requires significant scientific, regulatory and ecological expertise, substantial financial resources, cooperating partners, and the ability to make long-term commitments. As a participating estuary, each of the 28 NEPs receive strong federal and state financial assistance and programmatic support in these areas - support which non-NEP estuaries do not receive.

Moreover, because the NEPs are collaborative partnerships of agencies, organizations, businesses, and others, the data reported for each NEP represents a comprehensive reporting of the restoration and creation activities undertaken by the partners. This demonstrates that the 28 NEPs are an appropriate measure of the most significant observed restoration activities in the U.S.

Additional project activities occur in non-NEP estuaries. To account for these activities, a corrective factor equal to the ratio of NEP estuary land area to non-NEP estuary land area is applied. The land area of the contiguous U.S. is 2,961,266 square miles[40]. Coastal counties represent 17 percent of this area[41]. Therefore, coastal counties in the contiguous U.S. cover approximately 503,415 square miles of land (17

---

[40] U.S. Census Bureau, https://www.census.gov/geo/reference/state-area.html

[41] NOAA's List of Coastal Counties for the Bureau of the Census Statistical Abstract Series, https://www.census.gov/geo/landview/lv6help/coastal_cty.pdf

percent of geographic extent). The land area of the 28 NEPs is 246,338 square miles[42]. The ratio of land area in NEPs to total land area of coastal counties is 49 percent (246,338/503,415). Because the NEPs represent the most advanced and most supported estuary programs (see expert opinions below), we discount the non-NEP estimate by 50 percent. A correction factor of 50 percent therefore more than adequately captures activity in the non-NEP estuaries and the total *OAy* is equal to 1.5 times the *OAy* for NEPs.

The Environmental Protection Agency maintains an on-line database of projects reported by the 28 NEPs. Four years of data were reviewed to calculate an average rate of adoption for 2009 through 2012, which was then applied to the 2000 to 2014 period. This time period includes a one-time, significant infusion of federal government funding for estuary restoration in 2009. Through the American Recovery and Reinvestment Act of 2009, the National Oceanic and Atmospheric Administration received $165 million for projects, which had to be completed within 12-18 months. This one-time investment in restoration is highly unusual over the past 14 years (since the NEP data was first captured in 2000). Including this anomalous year in establishing an average adoption rate for the selected time period is a conservative approach to estimating activity penetration because it yields an average rate of restoration that is higher than the most likely rate, and applies that rate to the entire time period for determining *OAy*.

All United States estuaries face a common set of barriers to tidal wetland restoration including insufficient funding, lack of willing landowners and community support, and physical and ecological limitations and changes, such as sea level rise (Vigmostad *et al* 2005, Restore America's Estuaries and the Estuarine Research Federation, undated). In 2000, recognizing the critical need to provide funding for estuary habitat restoration, including tidal wetlands, and help to counter the mentioned socio-economic factors, the United States Congress passed and President Clinton signed into law, the Estuary Act of 2000, which authorized $275 million over five years for restoration activities.

OA*y* Method of Analysis

OAy for the NEPs was determined through a systematic review of the data sets provided by the EPA for each of the NEPs. In reviewing each data set, the analysis only includes project acreage resulting from projects, which (1) are not required by any rule, regulation, law, statute, court settlement or other mandatory action and (2) meet the definition of tidal wetland restoration provided in this methodology. Where a project description included multiple habitat types (eg, tidal wetland, shoreline, agriculture, etc.) and/or the project description included one or more activities in addition to restoration (eg, acquisition and barrier removal), the entire project acreage was included in the calculation. This is conservative because it will lead to a higher activity penetration. The NEP *OAy* calculation is provided in Table A1.

[42] National Estuary Program Coastal Condition Report, Chapter 2: Condition of National Estuary Program Sites - A National Snapshot, June 2007, http://water.epa.gov/type/oceb/nep/upload/2007_05_09_oceans_nepccr_pdf_nepccr_nepccr_natchap.pdf

Sources:

1. All 2009 data are from "NEP Project Information and Maps 2000-2009," http://gispub2.epa.gov/NEPMap/archivetree/archivetree.html. (U.S. Environmental Protection Agency). From each table, only tidal wetland restoration and creation projects are counted.
2. All 2010, 2011 and 2012 data are from the "NEP Projects Table Tool," http://gispub2.epa.gov/NEPmap/NEPTable_allyears/index.html. (National Estuary Program). From each table, only tidal wetland restoration and creation projects are counted.

Once the *NEP OAy* was determined, to ensure capture of non-NEP activities, it is increased by 50 percent for the Activity Penetration calculation.

$OAy = NEP\ OAy \times 1.5 = 97{,}422.17$ acres * 1.5 = 146,133 acres

Maximum Adoption Potential

To determine *MAPy*, an estimate of the available area for tidal wetland restoration needs to be established. The starting point for this estimate is the "Projected Impact of Relative Sea Level Rise on the National Flood Insurance Program" prepared by the Federal Emergency Management Agency (FEMA

1991). FEMA calculated the area of coastal floodplain that would flood under a 100-year coastal flood event for 1990 to be 19,500 mi^2 (12,800,000 acres). A 100-year flood event is defined as a flood that statistically has a 1 percent chance of occurring in any given year. By definition, the coastal floodplain does not include either upland areas or existing wetland areas (wetland areas do not flood because they are already regularly inundated). The coastal floodplain consists substantially of former wetland areas that were drained and/or filled and converted to other land uses, such as agricultural, commercial, or residential uses. This area includes many but not all former tidal wetland areas that were diked or drained for agriculture and other uses (some former wetland areas are no longer in the floodplain as they are now well protected by dikes or levees, eg, and therefore are not included in this estimate, which is conservative). Not all of the coastal floodplain area identified by FEMA is restorable or suitable for wetland creation. But for establishing an estimate of *MAPy*, 33 percent of this area (4,224,000 acres) is used as a conservative (low) estimate.

The FEMA estimate was made in 1991 and only includes land areas subject to flooding. Therefore, we also include in the *MAPy* tidal wetland losses since 1991 and tidal wetlands that have drowned or converted to open water in coastal Louisiana. Virtually all of these areas are suitable for tidal wetland restoration.

Louisiana wetland losses from 1900 to 1978 are reported to be 901,200 acres (U.S. Department of the Interior 1994). The *MAPy* estimate does not include Louisiana coastal wetland losses between 1978 and 1986, and it is conservative to exclude that area from the *MAPy*.

Tidal wetland losses from 1986 to 1997 were reported to be 8,450 acres (Dahl 2000). The 1991 to 1997 portion of these losses is assumed to be 4,225 acres, a pro-rated portion of the total.

Tidal wetland losses from 1998 to 2004 were reported to be 32,400 acres (Dahl 2006).

Tidal wetland losses from 2004 to 2009 were reported to be 124,290 acres (Dahl 2011).

No data exists for 2010 to 2013 (four years). We apply the average rate of loss from the previous five year period, 2004 to 2009, which is 124,290 acres /6 years = 20,715 acres /year.

Table A: Calculation of Maximum Adoption Potential for tidal wetland restoration (non-seagrass)

Maximum Adoption Potential	Acres
33% of FEMA 1991 Floodplain Estimate	4,244,000
Louisiana Delta Wetland Losses	901,200
Tidal Wetland Losses 1991 to 1997	4,228
Tidal Wetland Losses 1998 to 2004	32,400
Tidal Wetland Losses 2004 to 2009	124,290
Tidal Wetland Losses 2010 to 2013	82,860
Total MAPy (non-seagrass)	5,388,978

Activity Penetration Calculation for Tidal Wetlands (non-seagrass)

$APy = OAy / MAPy$

APy = 146,133 acres / 5, 338,978 acres

APy = 2.71%

Justification for Seagrass Meadow Restoration Penetration Levels

OAy Method of Analysis

Seagrass meadow restoration also occurs at a very low level relative to its maximum adoption level in the U.S. Evidence of this is provided by the National Oceanic and Atmospheric Administration, which maintains a Restoration Atlas (NOAA 2014). NOAA is the lead federal agency mandated with coastal and marine fisheries habitat restoration and protection, including seagrass meadow habitat. NOAA's level of funding for seagrass meadow restoration is therefore a sufficient estimate of the total level of seagrass restoration.

The NOAA database contains information on about 2,701 habitat projects that have occurred since 2000, and only 120, or 4 percent, are seagrass meadow projects. The database includes numerous habitats (eg, dune, in-stream, kelp, mangrove, oyster reef) as well as numerous activities in wetland habitats (restoration, invasive species removal, marine debris removal). Only a portion of the 120 seagrass meadow projects would meet the applicability conditions of this methodology. Therefore, including all of identified seagrass meadow restoration projects is conservative. The total acreage of estuary habitat restoration projects in the NOAA database is 49,837 acres. Seagrass meadow projects are typically conducted at a smaller scale than other habitat activities; therefore assuming that 4 percent of the total acreage can be attributed to seagrass restoration is conservative. The *OAy* for seagrass restoration is therefore 4 percent of 49,837 = 1,993 acres.

Maximum Adoption Potential Method of Analysis for Seagrass Restoration

Waycott *et al* (2009) demonstrated that seagrass meadow habitat losses in the U.S. were 853,845 acres between 1937 and 2006. The primary causes of the loss of seagrass meadows – sediment deposition, declining water quality, scarring from vessels, and disease – are typically reversible. Therefore, all of the area documented as lost is restorable. *MAPy* for seagrass meadow restoration is therefore 853,845 acres.

Activity Penetration Calculation for Seagrass Restoration

$APy = OAy / MAPy$

APy = 1,993 / 853,845 = 0.2%.

Expert Credentials

Debbie DeVore is the Gulf Restoration Program Coordinator for the US Fish & Wildlife Service, where she coordinates restoration activities for the Service offices and programs along the Gulf Coast. She has more than 15 years of experience in coastal resource management and has received numerous awards in her career.

Curtis D. Tanner is Acting Manager for the Division of Environmental Assessment and Restoration (EAR) in the U.S. Fish and Wildlife Service, where he manages staff and activities in the Watershed Protection and Restoration Branch. He provided leadership for the Puget Sound Nearshore Ecosystem Restoration Project, and has more than twenty years of experience in coastal resource management and restoration.

EXPERT OPINION I

Debbie L. DeVore
Gulf Coast Restoration Program Manager
U.S. Fish & Wildlife Service

Question 1 – To what extent do estuaries without a National Estuary Program face the same barriers to tidal wetland restoration activities as estuaries, which are part of a National Estuary Program? We have identified the following barriers, among others: funding, land ownership/control, political will, a local environment, which encourages partnerships, and social acceptability. Please note that we only need to consider barriers to tidal wetland restoration where it has already been identified as possible in the landscape. Based on your experience and expert judgment, do estuaries in NEPs face the same or similar barriers to implementation of tidal wetland restoration projects as estuaries that do not have an NEP? Please explain.

Answer:

While there are, no doubt, advantages afforded an estuary which has an established National Estuary Program (NEP) this does not preclude or exempt projects in these geographies from many of the same hurdles that projects face in an estuary outside the geographic of an NEP.

For example, funding is commonly the largest limiting factor in bringing a tidal restoration project to implementation, regardless of the project's location. Projects with involvement from an NEP must apply for the same limited funding as any other project (raising the same amount of match, etc.) and be held to the same reporting and fiduciary responsibilities as well. NEP supported projects must also go through the same scrutiny to obtain regulatory permission to conduct work, just as a non-NEP project does.

Both political will and public support for projects are also similar issues faced by projects both within an NEP and outside a NEP geography. In fact, projects with NEP support or in a NEP geography may even sometimes have a bigger stigma as the public may not have a high level of trust for governmental organizations and be much less supportive of their actions. As well, working with landowners (particularly private landowners) may prove more difficult for projects with an governmental agency connection.

Tidal restoration projects and activities, while often a high priority based upon the result of natural resource partners coming together for a common restoration objective, are not necessarily given special preference towards implementation simply because they are facilitated by such a collaboration. These projects are held to the same standards (and hence work through the same barriers and hurdles) as projects in a non-NEP geography.

Question 2 – How likely is it that the rates of restoration in National Estuary Programs are greater than the rates of restoration occurring in non-NEP estuaries in the U.S.? It is our assumption that NEPs will have an overall higher rate of restoration than other estuaries because NEPs benefit from a shared state and federal commitment to estuary health, which may be absent in other estuaries. Moreover, because of the status of being an NEP, they are more likely to receive scarce federal and state resources, as well as funding from other partners. NEPs are multi-stakeholder collaborative efforts that are not found in other estuaries in the U.S. Based on your experience and expert judgment, are NEPs substantially likely to have a higher rate of restoration than non-NEP estuaries? Please explain.

Answer:

Although I may paint a picture of hard times for NEPs above - having to jump through the same regulatory hoops as other projects - that is part of doing business in coastal restoration. NEPs and their restoration partners understand this and support that we should be held to the same regulatory and accountability standards as projects in non-NEP geographies or with no connection to the Program itself. NEPs and their partners do, however, recognize the tremendous benefit to a voluntary, collaborative and strategic approach to tidal restoration (as well as other coastal conservation issues NEPs address). Many funding agencies give credit to project proponents who work as a collective multi-stakeholder partnership. There is an assumption that such a partnership represents an agreed upon set of goals, objectives, implementation procedures and monitoring for a given project. This gives a funding agency a certain level of confidence that the project will be successful and supported at a local level. Project proposals written by NEP partners are also often more well defined and in concert with requested information outlined in a funding opportunity.

To answer your question specifically, yes, I do think NEPs have a higher likelihood of receiving funds for coastal restoration. I say this for a few reasons. In today's world of limited federal and state budgets and fewer dollars to put "on-the-ground" for projects, the conservation community has been pushed to become much more strategic in our thinking. By this I mean that we are looking at how projects fit into the larger watershed or landscape, we strive to accomplish as many partners' goal and objectives as possible, and we must leverage our funds as much as we possibly can. The NEP structure, their associated advisory committees and public outreach capabilities, lends itself to a role in facilitating such a strategic approach.

I worked for the FWS Coastal Program nearly 10 years and can say that for many of the reasons I described above, our Program encourages and actively engages in partnership with our local NEPs. In my tenure with the Coastal Program I have worked with NEPs in both Texas and Florida. When possible, our Program staff serve on technical advisory committees, participate in strategic planning and assist in project implementation. In fact, I was involved in drafting the current Strategic Plan for our southwest Florida focal area where I identified working with the NEPs as a priority for our Program. When appropriate and feasible, the Coastal Program has and continues to invest funding towards projects such as tidal restoration activities.

EXPERT OPINION II

Curtis Tanner
Acting Manager, Environmental Restoration and Assessment Division
U.S. Fish and Wildlife Service

18 November 2013

Steve Emmet-Mattox
Senior Director for Strategic
Planning and Programs
Restore America's Estuaries

Dear Steve:

I am writing in response to your September 23, 2013, email requesting my expert opinion regarding tidal wetland restoration and greenhouse gas offsets. As you know, I have over twenty years of experience working on coastal wetland restoration and protection for the U.S. Fish and Wildlife Service. The views expressed in this letter are based on my own experience and perspective, and do not reflect an official agency position. I have attached a copy of my current resume for your use in assessing my credentials.

As I understand it, you are working to establish the viability of tidal wetland restoration as a tool for use in sequestering carbon dioxide to mitigate anthropogenic greenhouse gas emissions. You seek to establish the fact that at a National scale, tidal wetland restoration in the United States is limited in spatial scale and impact. Specifically, "activity penetration", or the prevalence of restoration project implementation relative to the opportunity for tidal wetland restoration, is relatively small. In your assessment of tidal restoration in the U.S., you estimate the "…Activity Penetration is 1.06 percent, which is less than 5 percent, and therefore tidal wetland restoration in the U.S. is additional…" as defined by the Verified Carbon Standard. In short, you assert that given the relatively small amount of tidal wetland restoration in the U.S. (as compared to opportunity and demonstrated need), investment in restoration would provide a viable alternative for carbon offset funds. I concur with your assessment.

Your analysis relied upon the most comprehensive data set available at the National level for tidal wetland restoration, accomplishment reporting from the National Estuary Program (NEP). You have specifically requested that I provide an assessment based on my experience and expert judgment whether use of these data are appropriate. First, you have asked whether estuaries covered by the NEP provide a representative sample, facing the same or similar barriers to tidal wetland restoration project implementation. Based on 20+ years of experience working on coastal restoration and protection issues and projects, it is my opinion that tidal wetland restoration is typically limited by a set of barriers common to estuaries throughout the United States; funding, land owner willingness, and social acceptability are nearly universal challenges for all projects and estuaries. Taken together as a whole, the geographic distribution of NEP sites provides a broad cross section of National estuarine ecosystem conditions, encompassing a range of ecological threats, fish and wildlife resource assets, and socio/political contexts.

This representative diversity applies to both human and non-human aspects of coastal ecosystems.

Second, you post the question as to whether the rate of restoration derived from analysis of NEP estuaries is representative. As I understand your analysis, if NEP estuaries had a substantially lower rate of restoration than non-NEP estuaries, your activity penetration estimate of 1.06 percent, as compared the VCS threshold of 5 percent, could be challenged. Based on my experience derived from project implementation and program management, NEP estuaries likely deliver a higher rate of restoration as compared to non-NEP estuaries, if significant differences do in fact exist. I base this assertion on observations of the opportunity space provided for restoration that NEP designation provides coastal ecosystems. The Clean Water Act directs each NEP to develop and implement a Comprehensive Conservation and Management Plan (CCMP). Agencies including the U.S. Fish and Wildlife Service respond to policies and Congressional funding directives to focus restoration efforts in NEP systems, often in response to the CCMP. NEP designation also works to focus the work of state agency, tribal government, and non-governmental organization partners to address restoration needs defined by the CCMP. In Puget Sound, development and implementation of the CCMP is the role of the Puget Sound Partnership (PSP), a Washington State cabinet-level agency. PSP has led development of the current CCMP for Puget Sound, referenced as the “Action Agenda”. PSP’s Action Agenda includes specific targets for estuarine restoration required to recover the health of Puget Sound. Other non-NEP coastal ecosystems in Washington State lack this political focus and dedicated state and National funding for tidal wetland restoration.

In summary, while I have not provided a detailed review of your data sources and analysis, I am familiar with the approach you have applied in your analysis. NEP estuaries provide applicable data set for your assessment of activity penetration for restoration. CCMP’s for NEP estuaries provide a numeric objective for restoration and thus a quantifiable estimate of opportunity and need. Accomplishment reporting required by U.S. EPA delivers an accounting of acres restored which can be compared to numeric targets. The 28 NEP systems distributed throughout the United States provide a representative cross section of coastal ecosystems and the challenges and opportunities faced by restoration projects proponents. NEP designation leads to a regional focus of efforts, that delivers activity penetration rates likely equal or greater than that of non-NEP systems.

Thank-you for the opportunity to provide my perspective on your assessment. Please contact me directly if you have questions or if I can be of additional assistance.

Sincerely,
Curtis D. Tanner

Subject: expert guidance sought, Restore America's Estuaries tidal wetland restoration and ghg offsets

Dear Mr. Tanner,

Restore America's Estuaries is seeking to demonstrate the "additionality" of tidal wetland restoration in the U.S. for the purposes of generating carbon offsets under the Verified Carbon Standard. The VCS revised its rules in 2012 to include a standardized approach to demonstrate additionality. In order to comply with this approach, RAE has assembled a substantial data set and analysis. The data, analysis and discussion are attached. In a recent review by the VCS, they raised two questions that we would like your help in answering. I believe you to be an expert in tidal wetland restoration activities in the U.S., and now seek your opinion on the following:

1 – to what extent do estuaries without a National Estuary Program face the same barriers to tidal wetland restoration activities as estuaries, which are part of a National Estuary Program? We have identified the following barriers, among others: funding, land ownership/control, political will, a local environment, which encourages partnerships, and social acceptability. Please note that we only need to consider barriers to tidal wetland restoration where it has already been identified as possible in the landscape. Based on your experience and expert judgment, do estuaries in NEPs face the same or similar barriers to implementation of tidal wetland restoration projects as estuaries that do not have an NEP? Please explain.

2 – how likely is it that the rates of restoration in National Estuary Programs are greater than the rates of restoration occurring in non-NEP estuaries in the U.S.? It is our assumption that NEPs will have an overall higher rate of restoration than other estuaries because NEPs indicate a shared state and federal commitment to estuary health, which may be absent in other estuaries. Moreover, because of the status of being an NEP, they are more likely to receive scarce federal and state resources, as well as funding from other partners. NEPs are multi-stakeholder collaborative efforts that are not found in other estuaries in the U.S. Based on your experience and expert judgment, are NEPs substantially likely to have a higher rate of restoration than non-NEP estuaries? Please explain.

And last, please provide an up to date resume/CV, which we will share with the VCS.

Please let me know if you have any questions about this request, and thank you for your timely response.

Table of Contents

1 SUMMARY DESCRIPTION OF THE METHODOLOGY

Additionality and Crediting Method	
Additionality	Performance Method
Crediting Baseline	Performance Method

This methodology is applicable to projects which implement reduced impact logging practices to reduce greenhouse gas (GHG) emissions (hereafter termed *RIL-C practices*) in one or more of three GHG emission source categories (ie, timber felling, skidding and hauling). RIL-C practices may entail a range of improved logging and harvest planning practices, including, but not limited to, directional felling, improved log bucking (to permit greater recovery), improved harvest planning via pre-harvest inventory, skid trail planning and/or monocable winching, and reduction in width of haul roads and size of log landings.

The effectiveness of RIL-C practices, and accounting of emission reductions attributable to those practices, is assessed on the basis of their impacts post-harvest. Emission reductions are accounted for by applying a performance method approach, whereby emission reductions (net of baseline and project emissions) are assigned as a function of the difference between a set crediting baseline for each emission source category (ie, felling, skidding and hauling) and the measured impact of those parameters in the project scenario.

To ensure credible estimation of emission reductions, the impact parameters applied by this methodology are quantitative and outcome-based, rather than process-based (which are typically limited to demonstrating that the practice is in place, but may provide no information on how successful the implementation of the practice is). Further, emission reductions are estimated as a continuous function of the impact parameter values with which they correspond, providing better resolution of outcomes than a flat default factor. This methodology has been designed to ensure that emission reductions achieved based on one impact parameter are not reversed by excessive emissions with respect to another impact parameter, by requiring that all impact parameters must be at or below the crediting baseline in order for credits to be generated based on any one impact parameter.

Accounting is further simplified by incorporating the assumption that leakage equals zero and the wood products pool can be excluded because the methodology requires that there is no reduction in harvest levels.

Accounting is focused on emissions at the time of harvest from operations including felling, skidding and hauling, and delayed emissions from belowground biomass. Any net sequestration from comparatively improved growth post-RIL-C harvest is conservatively ignored.

Accounting of emission reductions begins on the project start date and is determined on all harvests through the project crediting period.

This document provides the framework for the methodology, and serves to outline core accounting procedures. Key parameters such as additionality benchmarks, crediting baselines, impact parameters, emission reduction equations and monitoring procedures are provided in corresponding geographic-specific RIL-C performance method modules. This methodology must be used in conjunction with a region-specific performance method module. The list of approved performance method modules applicable to this methodology can be found on the VCS website.

2 DEFINITIONS

In addition to the definitions set out in VCS document *Program Definitions*, the following definitions apply to this methodology:

Additionality Benchmark
The level of a given impact parameter below which a project is deemed additional, specified in terms of impact parameter values which represent a certain base level of performance among logging operations within a sampled logging landscape.

Crediting Baseline
The level of a given impact parameter below which emission reductions may be credited, specified in terms of impact parameter values which represent a certain base level of performance among logging operations within a sampled logging landscape. The corresponding baseline scenario is represented by an aggregate of individual logging operations from the logging landscape operating at this specified level of performance.

Impact Parameter
Quantitative parameter based on field measurements which defines both the crediting baseline and the additionality benchmark. Each impact parameter has an established empirical relationship with emissions levels, and is thus used as a proxy for emissions that can be readily measured in the field.

Logging Landscape
The geography, class of actors/sector, major logging system (eg, selective harvest) and timeframe within which the relationships of the impact parameter (with emission reductions) are applicable, and which is defined in the corresponding region-specific RIL-C performance method module.

Reduced Impact Logging (RIL-C)
Measures that reduce emissions from timber harvest in one or more of three emission source categories: felling, skidding and hauling. Component practices may include, but are not limited to, directional felling, improved log bucking, improved harvest planning via pre-harvest inventory, skid trail planning, mapping, and oversight and/or long cable winching, and reduction in width of haul roads and size of log landings.[1, 2]

3 APPLICABILITY CONDITIONS

This methodology applies to project activities which implement RIL-C practices in forests. Projects applying this methodology must meet the following applicability conditions:

1) The project activity does not involve a deliberate reduction in harvest levels. The criteria to demonstrate no intentional reduction in harvest level are provided in the applicable RIL-C performance method module.
2) The project activity and the baseline scenario do not involve conversion of forest to a non-forest land use/land cover (ie, both represent forests remaining as forests, *sensu* IPCC GL 2006).
3) In every year credited, the project proponent must hold legal authorization for all logging activities referenced in the project from the relevant government authority.
4) The project area must be located in a logging landscape developed for a corresponding region-specific RIL-C performance method module. It must be demonstrated that the entire project area is contained within the applicable logging landscape.
5) The entire project area meets the definition of forest, either host country-specific, UNFCCC or FAO definition.
6) RIL-C practices implemented as part of the project activity must not increase business-as-usual levels of impact on pre-existing dead wood stocks through slash management, salvage harvesting or other planned removal of dead wood.[3]

Requirements for developing a new region-specific performance method can be found in 0.

[1] Note that some practices may apply to more than one emission source category. Directional felling, for example, can serve to align logs with the planned skidding network, reducing skidding damage, and reduce damage to the felled log, improving roundwood recovery.

[2] Note that RIL-C practices do not include slash management, salvage harvesting or other planned removal of dead wood.

[3] VVBs need only confirm that this is the case through one of the following: a qualitative assessment of no evidence of removal of dead wood onsite (ie, looking for evidence of removal, or comparing dead wood carbon stocks in the project area to surrounding areas), interviewing project proponents, reviewing management plans, or a quantitative assessment of inventory data of dead wood carbon stocks (if they exist).

4 PROJECT BOUNDARY

Geographic boundary

The project area is defined as the area over which the project proponent holds authorization to conduct timber harvest over the length of the project crediting period. The area in its entirety must meet the definition of *forest* (see Section 3 above for definition of *forest*). The project area may be a subset of the concession holdings of the project proponent, but that the full extent of the project area must be defined at validation.

The boundary of the project area must be clearly delineated and documented with digital maps in the format specified by the VCS rules.

Temporal boundary

The temporal boundary of the project is set from the project start date, marking the initial harvest on which RIL-C practices are implemented, and the end of the project crediting period.

Pools and Sources

Table 1 below discusses the carbon pools included in the project boundary. Pools included in the project boundary are restricted to above- and below-ground tree biomass.

Table 2 below discusses the emission sources that are included in the project boundary. Emissions from fossil fuel combustion are conservatively excluded. Note that there are no optional pools, and that the included pools/sources (above- and belowground tree biomass) are accounted in both the baseline and project scenarios.

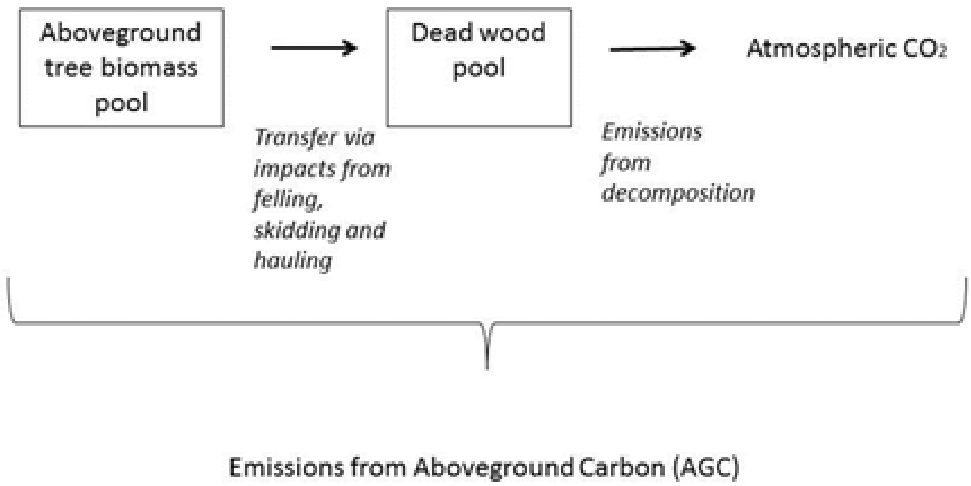
Table 1: GHG Pools Included in or Excluded from the Project Boundary

Carbon pools	Included?	Justification/Explanation
Aboveground tree biomass (included in *aboveground carbon*, AGC)	Yes	Must be included – represents a significant pool affected by the project activity
Aboveground non-tree biomass	No	Conservatively excluded – this pool is expected to increase relative to the baseline as a result of the project activity (from reduced skidding damage)
Belowground biomass	Yes	Must be included in all cases – represents a significant pool affected by the project activity

Dead wood (included in *aboveground carbon*, AGC)	Yes	Standing and lying dead wood produced by harvest are included. Changes in stocks of pre-existing dead wood are conservatively ignored (further explained below).
Harvested wood products	No	Applicability condition 1 obviates the inclusion of the wood products pool because there is no difference in harvest levels between the baseline and project scenarios.
Litter	No	No significant change is expected in this pool as a result of the project activity
Soil	No	No significant change is expected in this pool as a result of the project activity

Aboveground carbon stocks include both live and dead (standing and lying) pools. Emission reductions quantified for the aboveground carbon pool represent transfer of biomass carbon from live trees to dead wood, followed by steady emissions via decomposition, without explicitly separating the accounting of these elements, as described in Figure 1 below.

Figure 1: Schematic of Pools and Fluxes Incorporated in Aboveground Carbon (AGC) Emissions



Emissions from the dead wood pool included in accounting are from dead wood produced during harvest (ie, slash and new standing dead wood from harvest and collateral damage). This methodology conservatively does not account for changes in pre-existing standing and lying dead wood after harvest; these stocks would be expected to be greater in the project scenario post-harvest due to less-impactful RIL-C practices. As RIL-C practices implemented as part of the project activity do not include slash management, salvage harvesting or other planned removal of dead wood, this assumption is further assured.

Table 2: GHG Emission Sources Included In or Excluded From the Project Boundary

Source		Gas	Included?	Justification/Explanation
Baseline	Fossil fuel emissions	CO_2	No	Conservatively excluded - project activity is expected to result in lower emissions (from more efficient use of skidders) from use of machinery
		CH_4	No	Conservatively excluded - project activity is expected to result in lower emissions (from more efficient use of skidders) from use of machinery
		N_2O	No	Conservatively excluded - project activity is expected to result in lower emissions (from more efficient use of skidders) from use of machinery
Project	Fossil fuel emissions	CO_2	No	Same as for baseline scenario
		CH_4	No	Same as for baseline scenario
		N_2O	No	Same as for baseline scenario

5 BASELINE SCENARIO

The baseline scenario is established by the applicable region-specific RIL-C performance method module, and represents logging operations in aggregate, operating at a specified level of performance, for the referenced logging landscape. The baseline scenario is represented by region-specific crediting baselines set for each impact parameter (ie, proxy factor) by the applicable region-specific RIL-C performance method module.

6 ADDITIONALITY

This methodology uses a performance method for the demonstration of additionality.

Step 1: Regulatory Surplus

The project proponent must demonstrate regulatory surplus in accordance with the rules and requirements regarding regulatory surplus set out in the latest version of the *VCS Standard*.

Step 2: Performance Benchmark

Projects must exceed the region-specific performance benchmark for each impact parameter (ie, proxy factor), as provided in the applicable RIL-C performance method module. One or more impact parameters are defined in the applicable RIL-C performance method module for each of three categories: felling impacts, skidding impacts and hauling impacts.

Projects may only be credited for emission reductions from one or more impact parameters if they are deemed additional. A project is deemed additional for one or more impact parameters if the impact parameter is below the additionality benchmark assigned for that impact parameter. **The project may only be credited for emission reductions if all impact parameters are at or below their respective crediting baselines.**

This benchmark threshold should be conservative and strike a balance between restriction of freeriders and feasibility of participation. This threshold may be different from (ie, lower than) the crediting baseline. Thus, while a project must be below the additionality benchmark in order to receive any emission reductions credits, once below the additionality benchmark, the amount of credits generated is measured using the crediting baseline.

7 QUANTIFICATION OF GHG EMISSION REDUCTIONS

7.1 Baseline and Project Emissions

Baseline and project emissions are addressed simultaneously, whereby an emission reduction value (specified in tonnes of CO_2 reduced (ie, net of baseline and project emissions)) is assigned as a function of the difference between the impact parameter (proxy variable) in the project and in the crediting baseline for each emission source category (felling, skidding and hauling). Assigned emission reductions, expressed on a per hectare basis, are then summed for the three emission source categories, and multiplied by the number of hectares in the harvest area in year *t*.

Step 1: Determine Harvest Area

The harvest area in year *t* should be delineated on the basis of paper maps or GIS files specifying the actual harvest area in year *t*. From this area, the project proponent must delineate and exclude any areas where timber harvest impacts will not happen for any reason (eg, due to geographic features, low stocking, set asides or poor planning). The resulting area is specified in hectares to produce parameter A_t.

Step 2: Calculate Emission Reductions Based on Measured Impact Parameters

Calculate emission reductions for each emission source category based on measured impact parameters. Each equation below calculates emission reductions in tCO_2/ha (the dependent variable) as a function of (ie, f_{AGC}) a specific impact parameter (the independent variable). Functions and corresponding units are provided in the applicable region-specific RIL-C performance method module.

$$\mathrm{ER_{fell\_AGC,t} = f_{AGC}\ (FELL_t)} \tag{1}$$

$$\mathrm{ER_{skid\_AGC,t} = f_{AGC}\ (SKID_t)} \tag{2}$$

$$ER_{haul\_AGC,t} = f_{AGC}\ (HAUL_t) \tag{3}$$

$$ER_{fell\_BGB,t} = f_{BGB}\ (FELL_t) \tag{4}$$

$$ER_{skid\_BGB,t} = f_{BGB}\ (SKID_t) \tag{5}$$

$$ER_{haul\_BGB,t} = f_{BGB}\ (HAUL_t) \tag{6}$$

Where:

$FELL_t$	= Felling impact parameter measured in year *t* (unit specified in performance module)
$SKID_t$	= Skidding impact parameter measured in year *t* (unit specified in performance module)
$HAUL_t$	= Hauling impacts measured in year *t* (unit specified in performance module)
$ER_{fell\_AGC,t}$	= Emission reductions from aboveground carbon related to felling in year *t* (t CO_2e/ha)
$ER_{skid\_AGC,t}$	= Emission reductions from aboveground carbon related to skidding in year *t* (t CO_2e/ha)
$ER_{haul\_AGC,t}$	= Emission reductions from aboveground carbon related to hauling in year *t* (t CO_2e/ha)
$ER_{fell\_BGB,t}$	= Emission reductions from belowground biomass related to felling in year *t* (t CO_2e/ha)
$ER_{skid\_BGB,t}$	= Emission reductions from belowground biomass related to skidding in year *t* (t CO_2e/ha)
$ER_{haul\_BGB,t}$	= Emission reductions from belowground biomass related to hauling in year *t* (t CO_2e/ha)
t	= 1, 2, 3, …*t* time elapsed since the start of project activity (years)

Step 3: Sum Emission Reductions

Sum all emission reductions to determine the combined emission reductions from above- and belowground biomass.

For any time *t,* if any impact parameter is greater than or equal to the crediting baseline for that year, parameters $RILC_{,AGC,t}$ and $RILC_{,BGB,t}$ must be set to zero.

$$\mathrm{RILC_{AGC,t} = ER_{fell\_AGC,t} + ER_{skid\_AGC,t} + ER_{haul\_AGC,t}} \quad (7)$$

$$\mathrm{RILC_{BGB,t} = ER_{fell\_BGB,t} + ER_{skid\_BGB,t} + ER_{haul\_BGB,t}} \quad (8)$$

If ER_{Fellt} and/or ER_{Skidt} and/or ER_{Hault} < 0 then $RILC_{AGCt}$ = 0 and $RILC_{BGBt}$ = 0.

Where:

$RILC_{,AGC,t}$ = Combined emission reductions from aboveground carbon from RIL-C in year *t* (t CO_2e/ha)

$RILC_{,BGB,t}$ = Combined emission reductions from belowground biomass from RIL-C in year *t* (t CO_2e/ha)

$ER_{fell\_AGC,t}$ = Emission reductions from aboveground carbon related to felling in year *t* (t CO_2e/ha)

$ER_{skid\_AGC,t}$ = Emission reductions from aboveground carbon related to skidding in year *t* (t CO_2e/ha)

$ER_{haul\_AGC,t}$ = Emission reductions from aboveground carbon related to hauling in year *t* (t CO_2e/ha)

$ER_{fell\_BGB,t}$ = Emission reductions from belowground biomass related to felling in yer *t* (t CO_2e/ha)

$ER_{skid\_BGB,t}$ = Emission reductions from belowground biomass related to skidding in year *t* (t CO_2e/ha)

$ER_{haul\_BGB,t}$ = Emission reductions from belowground biomass related to hauling in year *t* (t CO_2-e/ha)

t = 1, 2, 3 …*t* time elapsed since the start of project activity (years)

Step 4: Determine Emission Reductions by Harvest Area

Emissions from aboveground carbon result from transfer of aboveground live biomass to the dead wood pool followed by steady decomposition.

Emission reductions from the aboveground carbon pool are determined either by applying an applicable dead wood decomposition rate, using equation 9a, or by applying a 10-year linear decay rate, using equation 9b.

Emission reductions from the belowground biomass pool must apply a 10-year linear decay rate (in both equations 9a and 9b). Thus, for a given year *t*, annual emission reductions from above- and belowground carbon are summed across areas previously harvested.

$$C_{RIL,t} = \sum_{t=1}^{t} A_t * RILC_{AGC,t} * (1-K)^{t-t*} * K + \sum_{t-10}^{t} A_t * RILC_{BGB,t} * (\frac{1}{10}) \quad (9a)$$

Where:

$C_{RIL,t}$ = Total emission reductions at time *t* (t CO_2e)

$RILC_{,AGC,t}$ = Combined emission reductions from aboveground carbon from RIL-C in year *t* (t CO_2e/ha)

$RILC_{,BGB,t}$ = Combined emission reductions from belowground biomass from RIL-C in year *t* (t CO_2e/ha)

K = Dead wood annual decomposition rate (percent/year)

A_t = Harvest area in year *t* (ha)

t = 1, 2, 3… *t* time elapsed since the start of the RIL project activity (years)

$$C_{RIL,t} = \sum_{t-10}^{t} A_t * RILC_{AGC,t} * (\frac{1}{10}) + \sum_{t-10}^{t} A_t * RILC_{BGB,t} * (\frac{1}{10}) \quad (9b)$$

Where:

$C_{RIL,t}$ = Total emission reductions at time *t* (t CO_2e)

$RILC_{,AGC,t}$ = Combined emission reductions from aboveground carbon from RIL-C in year *t* (t CO_2e/ha)

$RILC_{,BGB,t}$ = Combined emission reductions from belowground biomass from RIL-C in year *t* (t CO_2e/ha)

A_t = Harvest area in year *t* (ha)

t 1, 2, 3, …*t* time elapsed since the start of the RIL project activity (years)

***Ex-ante* Projections of GHG Emission Reductions**

At project validation and 10 year baseline re-assessment, an ex-ante estimate of GHG emission reduction must be produced in accordance with VCS rules. The projection will apply all calculations outlined above, incorporating impact parameters and functions to estimate emission reductions (ie, f_{AGC} and f_{BGB}) provided in the applicable region-specific RIL-C performance method module. Anticipated area harvested per year (A_t) will be referenced from annual authorized harvest areas specified in the project management authorization; it is understood that these areas may differ from the areas actually harvested ex post.

For each impact parameter (eg, $FELL_t$) that will be addressed through the project activity and for each year, the project proponent must assume a conservative level of effectiveness achieved, as a percent improvement from the crediting baseline value provided in the applicable region-specific RIL-C performance method module. The anticipated percent improvement is a value <1.0, and must be justified referencing specific operational management procedures and/or infrastructure to be put in place during project implementation.

For example, if a 30% improvement (indicating reduced emissions) from baseline is anticipated for a given impact parameter, and assuming that level of improvement meets the additionality benchmark, then multiply the crediting baseline value of the impact parameter by (1 – 0.30) = 0.70. The resulting value of the impact parameter is the basis for calculating emission reductions from the crediting baseline. Note that if a given impact parameter is constructed to increase from the baseline value with a decline in associated emission levels (rather than decline from baseline value with declining emissions as assumed above), then the example equation above would be modified accordingly.

7.2 Leakage

Since the applicability conditions do not allow for changes in harvest levels, it can be conservatively assumed that leakage is zero because there is no difference in harvest levels between the baseline and project scenarios.

7.3 Summary of GHG Emission Reduction and/or Removals

Uncertainty

Sources of uncertainty include uncertainty with respect to the calculation of emission reductions from impact parameters, and uncertainty with respect to estimates of impact parameters. These two sources of uncertainty are addressed by setting demonstrably conservative emission reductions associated with each impact parameter and through imposed minimum sampling intensity requirements for estimation of impact parameters, all established in the applicable region-specific RIL-C performance method module. Therefore, no uncertainty deduction is necessary. It is assumed that project area boundaries, A_t, are known exactly.

Net GHG emission reductions are calculated as follows:

$$ER_t = C_{RIL,t} \quad \textbf{(10)}$$

Where:

ER_T = Net GHG emission reductions in year *t* (t CO_2e)
$C_{RIL,t}$ = Total emission reductions at time *t* (t CO_2e)

Emission reductions eligible for issuance as Verified Carbon Units (VCUs) are calculated by subtracting the AFOLU pooled buffer account contribution from ER_t, referencing the project's risk rating at time *t* using the most recent version of the VCS *AFOLU Non-Permanence Risk Tool*.

8 MONITORING

The purpose of monitoring is to generate field measurements after each harvest from which emission reductions can be estimated. Thus, following completion of each harvest, all impact parameters from all logging emission source categories (felling, skidding and hauling), as identified in the applicable region-specific RIL-C performance method module, must be sampled in the field and estimated according to procedures detailed in the applicable region-specific RIL-C performance method.

Throughout the project crediting period, monitoring must be conducted within five years after each harvest unless otherwise specified in the applicable geographic-specific performance method module.

The expectation of users of this methodology and future modules developed based on this methodology is that verification audit teams are able to resample monitoring activities that have occurred over an entire verification period. The appropriate monitoring time frame will be dictated by regional forest regrowth rates and decomposition rates. For example, areas in dry forest with slow forest regrowth and decomposition may be able to monitor every 5 years, and areas in wet tropical forest with very fast growth rates and decomposition may need to be monitored every 2 years.

8.1 Data and Parameters Available at Validation

Data / Parameter	f_{AGC} $(FELL_t)$
Data unit	Dimensionless
Description	Equation estimating emission reductions from aboveground carbon related to felling in year *t* ($ER_{fell\_AGC,t}$) as a function of felling impacts measured in year *t* ($FELL_t$)
Equation	1
Source of data	Applicable RIL-C performance module

Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Refer to applicable RIL-C performance method
Purpose of data	Calculation of emission reductions
Comment	

Data / Parameter:	f_{BGB} $(FELL_t)$
Data unit	Dimensionless
Description	Equation estimating emission reductions from belowground carbon related to felling in year *t* $(ER_{fell\_BGB,t})$ as a function of felling impacts measured in year *t* $(FELL_t)$
Equation	4
Source of data	Applicable RIL-C performance module
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Refer to applicable RIL-C performance method
Purpose of data	Calculation of emission reductions
Comment	

Data / Parameter:	f_{AGC} $(SKID_t)$
Data unit	Dimensionless
Description	Equation estimating emission reductions from aboveground carbon related to skidding in year *t* $(ER_{skid\_AGC,t})$ as a function of skidding impacts measured in year *t* $(SKID_t)$
Equation	2
Source of data	Applicable RIL-C performance module
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Refer to applicable RIL-C performance method

Purpose of data	Calculation of emission reductions
Comment	

Data / Parameter:	f_{BGB} $(SKID_t)$
Data unit	Dimensionless
Description	Equation estimating savings factor for emissions from belowground carbon related to skidding in year t $(ER_{skid\_BGB,t})$ as a function of skidding impacts measured in year t $(SKID_t)$
Equation	3
Source of data	Applicable RIL-C performance module
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Refer to applicable RIL-C performance method
Purpose of data	Calculation of emission reductions
Comment	

Data / Parameter:	f_{AGC} $(HAUL_t)$
Data unit	Dimensionless
Description	Equation estimating savings factor for emissions from aboveground carbon related to hauling in year t $(ER_{haul\_AGC,t})$ as a function of hauling impacts measured in year t $(HAUL_t)$
Equation	3
Source of data	Applicable RIL-C performance module
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Refer to applicable RIL-C performance method
Purpose of data	Calculation of emission reductions
Comment	

Data / Parameter:	f_{BGB} $(HAUL_t)$
Data unit	Dimensionless
Description	Equation estimating savings factor for emissions from belowground carbon related to hauling in year t $(ER_{haul\_BGB,t})$ as a function of hauling impacts measured in year t $(HAUL_t)$
Equation	6
Source of data	Applicable RIL-C performance module
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Refer to applicable RIL-C performance method
Purpose of data	Calculation of emission reductions
Comment	

Data / Parameter:	K
Data unit	Percent/year
Description	Dead wood annual decomposition rate
Equation	9a
Source of data	Values from the literature (eg, Chambers *et al.* 2000) must be used
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	The rate used should be derived from a similar climate regime and forest type as the project area
Purpose of data	Calculation of emission reductions
Comment	Note that this rate is justified and applied in project accounting (using equation 9a ex post), and is not specified or incorporated in the RIL-C performance method modules.

8.2 Data and Parameters Monitored

Data / Parameter	A_t.
Data unit	Ha
Description	Area of actual harvest area in year *t.* It is expected that this area may be smaller than the authorized area of harvest due to un-stocked areas or areas where timber harvest and skidding are infeasible (eg, due to geographic features), or areas set aside from logging activity.
Equations	9a, 9b
Source of data	Paper maps or GIS files
Description of measurement methods and procedures to be applied	
Frequency of monitoring/recording	Following completion of each annual harvest
QA/QC procedures to be applied	Any imagery or GIS datasets used must be geo-registered referencing corner points, clear landmarks or other intersection points.
Purpose of data	Calculation of emission reductions
Calculation method	.
Comment	

Data / Parameter:	$FELL_t$
Data unit	Units as specified in the applicable RIL-C performance module
Description	Felling impact parameter, measured in year *t*
Equation	1, 4
Source of data	
Description of measurement methods and procedures to be applied	See procedures as specified in applicable RIL-C Performance Method
Frequency of monitoring/recording	Following completion of each annual harvest
QA/QC procedures to be applied	See applicable RIL-C performance module
Purpose of data	Calculation of emission reductions
Calculation method	

Comment	

Data / Parameter	$SKID_t$

APPENDIX 1: REGION-SPECIFIC PERFORMANCE METHOD REQUIREMENTS

Performance method modules may be developed for various geographies. General requirements for crediting and additionality benchmarks, and proxy emission reduction relationships, include:

1) The performance method must clearly specify the logging landscape and timeframe within which the values/relationships are applicable (ie, the sample population[4]). The logging landscape must be defined by broad parameters of consistent forest structure and composition (eg, the WWF Forested Ecoregions (Olson *et al.* 2001)).

2) The performance method must define additionality and crediting baselines in terms of impact parameters. Impact parameters must cover the following three sources of logging emissions: felling, skidding and hauling. One or more impact parameters may be identified for each of the three emissions source categories. When more than one impact parameter is identified for an emission source category, they must be measures of distinct (non-overlapping) components of that emissions source category.

3) The performance method must relate emission reductions to impact parameters and quantify and discount uncertainty in the dependent variable (ie, emission reductions). Emission reductions are calculated from (baseline) emissions associated with the crediting baseline value. Relationships between impact parameters and emission reductions must be developed for above and belowground tree biomass for each emission category (logging, felling and hauling) and expressed in units of tCO_2e/ha.

4) The performance method must specify monitoring procedures for all defined impact parameters.

An example of the derivation of applicable benchmarks and proxy relationships is provided in *VMD0047 Performance Method for Reduced Impact Logging (RIL-C) in East and North Kalimantan*.

[4] Note that conservative bias is allowed in sampling (ie, skewed toward logging operations allowing access to researchers).

Methodology for Rewetting Drained Temperate Peatlands

Version 1.0

17 July 2017

Sectoral Scope 14

The methodology was developed by:

Silvestrum Climate Associates

University of Greifswald

Partner in the Greifswald Mire Centre

Acknowledgements:

This methodology has been developed for (but is not limited to) use in the Belarus Peatland Rewetting Project ("BPR Project"). The development of this methodology was funded by the Federal Ministry for the Environment, Nature Conservation, Building and Nuclear Safety (BMUB), the University of Greifswald, Partner in the Greifswald Mire Centre, both Germany, and Silvestrum Climate Associates, The Netherlands. The methodology development was supported by BirdLife Belarus (APB), Centre for International Migration (CIM), Germany, and the Royal Society for the Protection of Birds (RSPB), United Kingdom.

1 SOURCES

The methodology makes use of the following approved methodologies and methodological tools[1]:

- CDM methodology *AR-ACM0001 Afforestation or reforestation of degraded land*
- CDM methodological tool *Calculation of the number of sample plots for measurements within A/R CDM project activities*
- CDM methodological tool *Combined tool to identify the baseline scenario and demonstrate additionality in A/R CDM project activities*
- CDM methodological tool *Tool for testing significance of GHG emissions in A/R CDM project activities*

This methodology uses the latest versions of the following module[2]:

- VCS module *VMD0019 Methods to project future conditions*

2 SUMMARY DESCRIPTION OF THE METHODOLOGY

Additionality and Crediting Method	
Additionality	Project Method
Crediting Baseline	Project Method

This methodology outlines procedures to estimate the reduction of net greenhouse gas emissions resulting from project activities implemented to rewet drained peatlands in temperate climatic regions. It allows for the estimation of GHG emissions from drained and rewetted peatlands and also accounts for changes in carbon stocks in selected non-peat carbon pools.

The scope of this methodology is essentially limited to project activities that aim at the rewetting of peatlands that have been drained for forestry, peat extraction or agriculture, but where these activities are not or no longer profitable. Post-rewetting land use is limited to forestry, agriculture, nature conservation/recreation, or activities limited to those aiming at GHG emission reductions, or a combination of these activities.

This methodology uses ground vegetation composition and water table depth as proxies for peatland GHG emissions, known as the 'GEST' approach (GEST: Greenhouse gas Emission Site Type). Vegetation is well qualified for indicating greenhouse gas fluxes (Couwenberg *et al.* 2011) due to the following:

- It is a good indicator of water table depth, which in turn strongly correlates with GHG fluxes;

[1] CDM tools are available at https://cdm.unfccc.int/methodologies/ARmethodologies/tools
[2] VCS modules are available at the VCS website.

- It is controlled by various other site factors that determine GHG emissions from peatland, such as nutrient availability, soil reaction (acidity) and land use (history);
- It is itself directly and indirectly responsible for the predominant part of the GHG emissions by regulating CO_2 exchange, supplying organic matter (including root exudates) for CO_2 and CH_4 formation, reducing peat moisture, and by providing possible bypasses for increased methane emission via aerenchyma ('shunt species');
- It reflects long-time water table conditions and thus provides indication of average GHG fluxes on an annual time scale;
- It allows fine-scaled mapping (e.g., at scales 1:2,500 – 1:10,000).

Procedures are provided for the estimation of the Peat Depletion Time (PDT) and the assessment of the maximum eligible quantity of GHG emission reductions by rewetting, and is based either on the difference between the remaining peat carbon stock in the project and baseline scenarios after 100 years (total stock approach), or the difference in cumulative carbon loss in both scenarios since project start (stock loss approach).

Transient peaks of CH_4 emissions after rewetting may occur. For their quantification, conservative estimates from peer-reviewed literature sources must be used.

This methodology addresses anthropogenic peat fires occurring in drained peatland and establishes a conservative default value (*Fire Reduction Premium*), based on fire occurrence and extension in the project area in the baseline scenario, so as to avoid the direct assessment of GHG emissions from fire in the baseline and the project scenarios.

Under the applicability conditions of this methodology, market leakage, activity shifting and ecological leakage do not occur and the methodology provides criteria for justification of the absence of such leakage.

The methodology provides for the determination of the project's net GHG benefits and the resulting Verified Carbon Units (VCUs) that are generated. The methodology details the steps necessary to come to the final calculation of the project's net GHG benefits, represented by NER_{RDP}.

$$NER_{RDP} = GHG_{BSL} - GHG_{WPS} + Fire\ Reduction\ Premium - GHG_{LK}$$

Where:

NER_{RDP}	Total net CO_2 equivalent emission reductions from the rewetting of drained peatland (RDP) project activity
GHG_{BSL}	Net CO_2 equivalent emissions in the baseline scenario
GHG_{WPS}	Net CO_2 equivalent emissions in the project scenario
Fire Reduction Premium	Net CO_2 equivalent emission reductions from peat combustion due to

	rewetting and fire management
GHG_{LK}	Net CO_2 equivalent emissions due to leakage

3 DEFINITIONS

Greenhouse gas Emission Site Type (GEST)
A combination of plant species indicating long-term water table depths and other characteristics relevant to GHG fluxes (e.g., peat type, pH, nutrient status), associated with annual mean GHG fluxes of carbon dioxide and methane (expressed as CO_2e) based on literature or country-specific measurements. In absence of vegetation, water table depth is used as the main proxy (Couwenberg *et al.* 2011).

Net Ecosystem Exchange (NEE)
An instantaneous measurement of the inward and outward flows of carbon within an ecosystem. NEE is measured by eddy-flux towers to determine the amount of CO_2 entering an ecosystem and the amount of carbon being lost through respiration simultaneously.

Net Ecosystem Production (NEP)
A measurement of the net gain (or loss) of carbon in a system over a period of time. NEP is estimated based on long-term averages of NEE measurements.

Peatland
The definition is provided in the *VCS Program Definitions*. For the purpose of this methodology, organic soils that do not meet the depth requirement in the used definition but that are connected to the peatland area may be deemed part of the peatland area included in the GHG accounting. Isolated areas of organic soil that do not meet the depth requirements are not considered peatland.

Water table depth[3]
Depth of sub-soil or above-soil surface of water, relative to the soil surface.

4 APPLICABILITY CONDITIONS

This methodology is applicable under the following conditions:

1) The project activity is the rewetting of drained peatland.
2) The project area:
   a) Meets the definition of a peatland;
   b) Is located in a temperate[4] climatic region.
3) The project area was drained for the following land use scenarios or a combination of the

[3] In other methodologies, this term may be referred to as ‘drainage depth’, where it is implied to have the same meaning.
[4] The GEST approach has, so far, only been developed for temperate climates.

following land use scenarios:

a) Forestry that is not or no longer profitable (as determined on the basis of annual reports, annual accounts, market studies, government studies, or land use planning reports and documents);

b) Peat extraction that has been abandoned at least 2 years prior to the project start date; and/or,

c) Agriculture that has been abandoned at least 2 years prior to the project start date or will be continued in the project, or where drainage of additional peatland for new agricultural sites will not occur or is prohibited by law.

4) Post-rewetting land use is limited to the following or a combination of the following:

   a) Forestry (including biomass production but excluding IFM and REDD activities);

   b) Agriculture (excluding ALM activities); and/or,

   c) Nature conservation/recreation.

5) The following activities may occur in the baseline scenario:

   a) Biomass burning.

6) The following activities must not occur in the baseline scenario:

   a) Harvesting for commercial purposes; or,

   b) Collection of firewood for commercial purposes.

7) The following activities may not occur in the project scenario:

   a) Peat extraction;

   b) Burning of peat;

   c) Burning of biomass; and,

   d) N-fertilizer usage.

8) Project design and site selection must include the following:

   a) Project GHG benefits are not negatively affected by drainage activities that occur outside the project area[5].

   b) Leakage caused by activity shifting, market effects and hydrological connectivity is avoided[6].

9) Live tree vegetation may be present and subject to carbon stock changes (e.g., due to harvesting) in both the baseline and project scenarios.

10) Where GHG emission reductions from reducing peat fires are claimed by the project, the following must be met:

[5] This is further specified in Section 5.2

[6] This is further specified in Section 8.4.

a) A threat of frequent on-site fires must be been demonstrated[7].

b) Where the default procedure provided by this methodology for assessing GHG emissions due to peat fires in the baseline scenario cannot be used, such baseline emissions must conservatively not accounted for; and,

c) Peatland rewetting must be combined with fire management.

11) It must be demonstrated by referring to peer-reviewed literature and by sufficient rewetting that N_2O emissions will not increase in the project scenario compared to the baseline scenario.

12) In the baseline scenario, the peatland must be drained.

5 PROJECT BOUNDARY

5.1 Temporal Boundaries

Project Crediting Period

The temporal boundary for projects applying this methodology is equal to the project crediting period. The project must have a robust operating plan covering this period.

Where emissions increase during a transient period after rewetting, this is regarded as a negative emission reduction and falls within the project crediting period.

Project proponents must determine the project crediting period, the project crediting period start date and the project start date and provide verifiable evidence to support these claims.

Peat Depletion Time (PDT)

Peat depletion may be accelerated by peat fires and is attained if the peat has disappeared or if a stable water table inhibits further oxidation of the peat. The PDT for a stratum in the baseline scenario equals the period during which the project can claim emission reductions from rewetting and is, per stratum *i*, at the project start date and at each reassessment of the baseline scenario (as outlined in Section 6.2) estimated as:

$$t_{PDT\text{-}BSL,i} = Depth_{peat\text{-}BSL,i} \,/\, Rate_{peatloss\text{-}BSL,i} \qquad \textbf{(1)}$$

Where:

$t_{PDT\text{-}BSL,i}$	PDT in the baseline scenario in stratum *i* in years elapsed since the project start; yr
$Depth_{peat\text{-}BSL,i}$	Average peat depth above the drainage limit in the baseline scenario in stratum *i* at project start; m

[7] RWE projects may generate GHG credits from the reduction of GHG emissions associated with avoiding peat fires on drained or partially drained peatlands.

$Rate_{peatloss\text{-}BSL,i}$	Rate of peat loss due to subsidence and fire in the baseline scenario in stratum *i*; a conservative (high) value must be applied; m yr^{-1}
i	1, 2, 3, … M_{BSL} strata in the baseline scenario

Peat depths, depths of burn scars and subsidence rates must be derived from data sources as described in Section 9.1.

5.2 Geographic Boundaries

Project proponents must define the project boundary at the beginning of a proposed project activity and must provide the geographical coordinates of lands to be included, so as to allow clear identification for the purpose of verification. Remotely sensed data, officially certified topographic maps, land administration and tenure records, and/or other official documentation that facilitates the clear delineation of the project boundary may be used.

The RDP project activity may contain more than one discrete area of land. Each discrete area of land must have a unique geographical identification.

When describing physical project boundaries, the following information must be provided per discrete area:

- Name of the project area (including compartment numbers, local name (if any))
- Unique identifier for each discrete parcel of land
- Map(s) of the area (preferably in digital format)
- The data must be geo-referenced, and provided in digital format in accordance with the VCS rules.
- Total area
- Details of land rights holder and user rights

Stratification

If the project area at the start of the project is not homogeneous, stratification may be carried out to improve the accuracy and the precision of peat depth, carbon stock and GHG flux estimates. Different stratifications may be required for the baseline and project scenarios in order to achieve optimal accuracy of the estimates of net GHG emissions or removals.

Strata are defined on the basis of peat depth (including eligibility as assessed below), water table depth (e.g., at 0 cm defining a level of zero emission, a deep water table depth defining the high end of emissions, and arbitrary levels in between), tree cover and/or vegetation composition, or expected changes in these.

In case of the presence of a tree cover, the GEST approach (Section 8.1.3) must be supplemented by procedures to estimate tree carbon stock change and therefore separate strata must be established for forested land. Furthermore, different GESTs give rise to different strata.

Stratification on the basis of peat depth must be based on a peat depth map for the entire project area. Existing peat depth maps can be used in combination with interpolation techniques to derive conservative peat depth maps of the required accuracy (see below). Stratification of the project area by peat depth is required:

a) When in more than 5% of the project area peat is absent or the depth of the peat is below a threshold value (e.g., 10 cm); the peat depth map only needs to distinguish where peat depth exceeds this threshold. It is conservative to omit shallow peat strata in accounting.

b) When, using a conservative (high) value for subsidence rates, in the project scenario in more than 5% of the project area the peat is depleted within 100 years ($\leq t$=100); the peat depth map only needs to distinguish where peat will be depleted at t=100.

c) When, using a conservative (high) value for subsidence rates, in the baseline scenario in more than 5% of the project area the project crediting period exceeds the PDT ; the peat depth map must distinguish with a depth resolution of 10 cm strata where peat will be depleted within the project crediting period. Areas where peat will not be depleted need not be further stratified.

No stratification on the basis of peat depth is required if the peat depth in 95% or more of the project area exceeds the required minimum peat depth for any of the above conditions.

Areas with a peat layer at project start shallower than required by the adopted definition of peatland may be included if such areas are connected with areas that meet the definition. Isolated pockets that do not meet the definition must not be included.

When using existing peat depth maps or data, these must be corrected, in a conservative way, for peat excavation and subsidence. When, after correction, strata exceed the required minimum peat depth by less than 50 cm, these strata must be verified using field observations (e.g., using a peat auger following the procedures to create a peat depth map outlined below).

To create a peat depth map, depth measurements must be conducted along transects that cover the peatland in a systematic way. Distance between transects must be 200 m at maximum. Starting from the peatland margin, the initial distance between depth observations along transects must not be greater than 100 m with a depth accuracy of at least 10 cm. When two subsequent depth observations along a transect fulfill the required depth criteria by a margin of at least 50 cm, the distance between transects and observation points can be raised to 500 m. Transects must cross the entire peatland and must be initiated from opposed margins. If transects cross mineral soil areas present inside a contiguous peat area, transects departing from these mineral soil areas must also have an initial distance between depth observations of not greater than 100 m. Peat depth maps must be based on peat depth measurements in combination with interpolation techniques to derive conservative peat depth maps of the required accuracy.

In case shallow peat areas are conservatively neglected, it is sufficient to conduct depth measurements that cover the peatland in a systematic way, with at least 4 measurement points per km^2 or at a distance of 500 m.

Strata must be spatially discrete and stratum areas must be known. Areas of individual strata must sum to the total project area. Strata must be identified with spatial data (e.g., maps, GIS coverage, classified imagery, or sampling grids) from which the area can be determined accurately. Land use/land cover maps in particular must be ground-truthed and less than 10 years old. Strata must be discernible taking into account good practice in terms of the accuracy requirements for the definition of strata limits / boundaries. This must be indicated in the project documentation and the choice must be justified.

The project area may be stratified *ex ante*, and this stratification may be revised *ex post* for monitoring purposes. Established strata may be merged if reasons for their establishment have disappeared or have proven irrelevant to key variables for estimating net GHG emissions or removals.

Baseline stratification must remain fixed until a reassessment of the baseline scenario occurs.

Stratification in the project scenario will be updated at each monitoring event prior to verification.

The area of channels and ditches must be quantified and treated as separate strata. CH_4 emissions from these channels and ditches will not increase in the project scenario compared to the baseline scenario (Couwenberg *et al.* 2011) and therefore, CH_4 emissions from these channels and ditches can be excluded from GHG accounting.

Peatland areas eligible for carbon crediting

The maximum eligible quantity of GHG emission reductions by rewetting is limited to the difference between the remaining peat carbon stock in the project and baseline scenarios after 100 years (total stock approach), or the difference in cumulative carbon loss in both scenarios over a period of 100 years since project start (stock loss approach). If a significant difference (≥ 5%) at the 100-years mark cannot be demonstrated, the project area is not eligible for carbon crediting. This assessment must be executed *ex ante* using conservative parameters.

The procedure assumes a variable rate of peat loss in the baseline and project scenarios, or, alternatively, a conservative – as explained in footnote 7 – value that remains constant over time, based on expert judgment[8], datasets and/or literature (see Section 9.1).

[8] Requirements for expert judgment are provided in Section 9.3.2.

1. Total stock approach

The difference between peat carbon stock in the project scenario and baseline scenario at t=100 is estimated as:

$$C_{WPS-BSL,t100} = \sum_{i=1}^{M_{WPS}} \left(C_{WPS,i,t100} \times A_{WPS,i,t100} \right) - \sum_{i=1}^{M_{BSL}} \left(C_{BSL,i,t100} \times A_{BSL,i,t100} \right) \quad (2)$$

$$C_{WPS,i,t100} = Depth_{peat\text{-}WPS,i,\,t100} \times VC_{peat} \times 10 \quad (3)$$

$$C_{BSL,i,t100} = Depth_{peat\text{-}BSL,i,\,t100} \times VC_{peat} \times 10 \quad (4)$$

$$Depth_{peat-BSL,i,t100} = Depth_{peat-BSL,i,t0} - \sum_{t=1}^{t=100} Rate_{peatloss-BSL,i,t} \quad (5)$$

$$Depth_{peat-WPS,i,t100} = Depth_{peat-WPS,i,t0} - \sum_{t=1}^{t=100} Rate_{peatloss-WPS,i,t} \quad (6)$$

If a conservative constant subsidence rate is applied, a possible negative outcome is substituted by zero.

Where:

$C_{WPS\text{-}BSL,t100}$	Difference between peat carbon stock in the project scenario and baseline scenario at t=100 ; t C
$C_{WPS,i,t100}$	Peat carbon stock in the project scenario in peat depth stratum i at t=100;t C ha^{-1}
$C_{BSL,i,t100}$	Peat carbon stock in the baseline scenario in peat depth stratum i at t=100; t C ha^{-1}
$Depth_{peat\text{-}BSL,i,t100}$	Average peat depth above the drainage limit in the baseline scenario in stratum i at t=100; m
$Depth_{peat\text{-}WPS,i,t100}$	Average peat depth above the drainage limit in the project scenario in stratum i at t=100; m
$Depth_{peat\text{-}BSL,i,t0}$	Average peat depth above the drainage limit in the baseline scenario in stratum i at project start; m
$Depth_{peat\text{-}WPS,i,t0}$	Average peat depth above the drainage limit in the project scenario in stratum i at project start; m
$Rate_{peatloss\text{-}BSL,i,t}$	Rate of peat loss due to subsidence and fire in the baseline scenario in stratum i at time t; alternatively, a conservative (low[9]) value may be applied that remains constant over time; m yr^{-1}

[9] Note that the use of a relatively low value for a constant rate of peat loss may not be confused with a relatively high value when determining the need for stratification of peat depth (p7).

$Rate_{peatloss,WPS,i,t}$	Rate of peat loss due to subsidence in the project scenario in stratum *i* at time *t*; alternatively, a conservative (high) value may be applied that remains constant over time; m yr^{-1}
VC_{peat}	Volumetric carbon content of peat; kg C m^{-3}
$A_{WPS,i,t100}$	Area of project stratum *i* at *t*=100; ha
$A_{BSL,i,t100}$	Area of baseline stratum *i* at *t*=100; ha
i	1, 2, 3, … M_{BSL} or M_{WPS} peat depth strata in the baseline scenario or project scenario
t_{100}	100 years since project start

The volumetric carbon content in peat can be taken from measurements within the project area or from literature involving the project or similar areas.

$C_{WPS,i,t100}$ needs no adjustments since under the applicability conditions leakage emissions are absent.

The difference between peat carbon stock in the project scenario and baseline scenario at *t*=100 ($C_{WPS-BSL,t100}$) is significant if:

$$\sum_{i=1}^{M_{WPS}}\left(C_{WPS,i,t100}\times A_{WPS,i,t100}\right)\geq 1.05\times\sum_{i=1}^{M_{BSL}}\left(C_{BSL,i,t100}\times A_{BSL,i,t100}\right) \quad (7)$$

<u>2. Stock loss approach</u>

As $Depth_{peat-BSL,i,t0} = Depth_{peat-WPS,i,t0}$ the assessment can also be based on cumulative subsidence up to *t*=100 as follows:

$$C_{WPS-BSL,t100}=\sum_{i=1}^{M_{BSL}}\left(C_{peatloss-BSL,i,t100}\times A_{BSL,i,t100}\right)-\sum_{i=1}^{M_{WPS}}\left(C_{peatloss-WPS,i,t100}\times A_{WPS,i,t100}\right) \quad (8)$$

$$C_{peatloss-BSL,i,t100}=10\times\sum_{t=1}^{100}\left(Rate_{peatloss-BSL,i,t}\times VC_{peat}\right) \quad (9)$$

$$C_{peatloss-WPS,i,t100}=10\times\sum_{t=1}^{100}\left(Rate_{peatloss-WPS,i,t}\times VC_{peat}\right) \quad (10)$$

Where:

$C_{WPS-BSL,t100}$	Difference between peat carbon stock in the project scenario and baseline scenario at *t*=100; t C
$C_{peatloss-BSL,i,t100}$	Cumulative peat carbon loss due to subsidence and fire in the baseline scenario in subsidence stratum *i* at *t*=100; t C ha^{-1}

$C_{peatloss\text{-}WPS,i,t100}$	Cumulative peat carbon loss due to subsidence in the project scenario in subsidence stratum *i* at *t*=100; t C ha^{-1}
$Rate_{peatloss\text{-}BSL,i,t}$	Rate of peat loss due to subsidence and fire in the baseline scenario in stratum *i* in year *t*; alternatively, a conservative (low) value may be applied that remains constant over time; m yr^{-1}
$Rate_{peatloss\text{-}WPS,i,t}$	Rate of peat loss due to subsidence in the project scenario in stratum *i* in year *t*; alternatively, a conservative (high) value may be applied that remains constant over time; m yr^{-1}
VC_{peat}	Volumetric carbon content of peat; kg C m^{-3}
$A_{WPS,i,t100}$	Area of project stratum *i* at *t*=100; ha
$A_{BSL,i,t100}$	Area of baseline stratum *i* at *t*=100; ha
i	1, 2, 3, … M_{BSL} or M_{WPS} subsidence strata in the baseline scenario or project scenario
t_{100}	100 years after project start

Using short-term or historic subsidence rates for the entire period of 100 years is conservative since subsidence rates are likely to decline over time (Stephens *et al.*, 1984).

The difference between peat carbon stock in the project scenario and baseline scenario at *t*=100 ($C_{WPS\text{-}BSL,t100}$) is significant if:

$$\sum_{i=1}^{M_{BSL}}\left(C_{peatloss-BSL,i,t100}\times A_{BSL,i,t100}\right)\geq 1.05\times\sum_{i=1}^{M_{WPS}}\left(C_{peatloss-WPS,i,t100}\times A_{WPS,i,t100}\right) \tag{11}$$

Buffer zones

Under the applicability conditions of this methodology, the project boundary must be designed such that the project GHG benefits are not affected by drainage activities that occur outside the project area (e.g., enhanced drainage, groundwater extraction, and changing water supply). This can be achieved either by an appropriate design (e.g., by establishing an impermeable dam) or by a buffer zone within the project boundary for which conservatively no GHG benefits are accounted. This buffer zone, if employed, must be mapped and is not eligible for carbon crediting. The size and shape of the buffer zone must be determined on the basis of quantitative hydrological modeling, or expert judgment.

Procedures for buffer zones against ecological leakage are provided in Section 8.4.

5.3 Carbon Pools

The carbon pools that are included and excluded from the project boundary are shown in Table 5.1.

In addition, carbon pools may be deemed *de minimis* and do not have to be accounted for if together the omitted decrease in carbon stocks or increase in GHG emissions (Table 5.2) amounts to less than 5% of the total GHG benefit generated by the project. Peer reviewed literature or the CDM A/R methodological tool *Tool for testing significance of GHG emissions in A/R CDM project activities* may be used to determine whether decreases in carbon pools are *de minimis*.

Table 5.1: Carbon Pools Included In or Excluded From the Project Boundary

Carbon pools	Included?	Justification/Explanation of choice
Above-ground tree biomass	Yes	Major carbon pool may significantly increase in the baseline, or decrease in the project, or both, in case of establishment or presence of tree vegetation. Tree vegetation in the baseline scenario must be included. Tree vegetation in the project scenario may be conservatively set to zero.
Above-ground non-tree biomass	Optional	This pool is only included if GESTs are based on vegetation cover. In such cases, changes in lower vegetation are included in the estimates of NEE (or NEP) represented by GESTs.
Below-ground biomass	Yes	Major carbon pool may significantly increase in the baseline, or decrease in the project, or both, in case of presence of tree vegetation Tree vegetation in the baseline scenario: must be included. Tree vegetation in the project scenario: may be conservatively set to zero. Lower (herb) vegetation: included in the NEE (or NEP).
Tree litter	Optional	The litter layer must only be included if it forms part of a GEST.
Wood products	Optional	This pool is optional.
Dead wood	Optional	This pool is optional.
Soil organic carbon	Yes	Major carbon pool subject to the project activity. The soil organic carbon component is represented by the peat component.

5.4 Greenhouse Gases

The emission sources included in or excluded from the project boundary are shown in Table 5.2.

In addition, GHG sources may be deemed *de minimis* and do not have to be accounted for if together the omitted decrease in carbon stocks (Table 5.1) or increase in GHG emissions amounts to less than 5% of the total GHG benefit generated by the project. Peer reviewed literature or the CDM A/R methodological tool *Tool for testing significance of GHG emissions in A/R CDM project activities* may be used to determine whether increases in GHG emissions are *de minimis*.

Table 5.2: GHG Sources Included In or Excluded From the Project Boundary

Source		Gas	Included?	Justification/Explanation
Baseline	Changes in stocks in carbon pools in biomass	CO_2	Yes	Potential major source of removals considered under carbon pools
	Oxidation of drained peat	CO_2	Optional	May be conservatively excluded in the baseline scenario
		CH_4	Optional	Potentially significant emission; may be conservatively excluded in the baseline scenario
		N_2O	No	Excluded as per applicability condition
	Burning of biomass	CO_2	No	Not accounting in baseline scenario is conservative
		CH_4	No	Not accounting in baseline scenario is conservative
		N_2O	No	Not accounting in baseline scenario is conservative
	Peat burning	CO_2	Yes	Fire may occur in the baseline scenario and is accounted for with a default approach
		CH_4	No	Conservatively excluded in the baseline scenario
		N_2O	No	Conservatively excluded in the baseline scenario
Project	The production of methane by bacteria	CH_4	Yes	Potential major source of emissions in the project in low salinity and freshwater areas

Source		Gas	Included?	Justification/Explanation
	Accumulation of peat in project scenario	CO_2	No	Conservatively excluded in the project scenario
	Burning of biomass	CO_2	No	CO_2 is addressed in carbon stock change procedures
		CH_4	No	Accounting in project scenario is excluded as per applicability condition
		N_2O	No	Accounting in project scenario is excluded as per applicability condition
	Fossil fuel combustion from transport and machinery use in project activities	CO_2	No	Deemed *de minimis*
		CH_4	No	Deemed *de minimis*
		N_2O	No	Deemed *de minimis*
	Peat burning	CO_2	Yes	Fire may occur in the project scenario and is accounted for with a *Fire Reduction Premium* approach
		CH_4	No	Not included in the *Fire Reduction Premium* approach
		N_2O	No	Not included in the *Fire Reduction Premium* approach

6 BASELINE SCENARIO

6.1 Determination of the Most Plausible Baseline Scenario

At the project start date, the baseline scenario must consist of drained peatland with a land use that can be forestry, peat extraction or agriculture, abandonment after such activities, or a combination of these, but where these activities are not or no longer profitable. Continuations of these land uses and possible subsequent changes in various alternative baseline scenarios are determined using the latest version of the CDM tool *Combined tool to identify the baseline scenario and demonstrate additionality in A/R CDM project activities*.

The tool has been designed for A/R CDM project activities, but must be used for the purpose of this methodology, noting the following:

Where the tool refers to	It must be understood as referring to
A/R, afforestation, reforestation, or forestation	WRC, or rewetting
Net greenhouse gas removals by sinks	Net greenhouse gas emission reductions
CDM	VCS
DOE	VVB
tCERs, lCERs	VCUs

Step 0 and Sub-step 2b – 15 (regarding forested areas since 31 December 1989) must be omitted. Footnote No 1-3 must be omitted[10].

In instances where there is a conflict between the CDM tool requirements and the VCS rules, the VCS rules must be followed.

6.2 Re-assessment of the Baseline Scenario

The project proponent must reassess the baseline scenario in accordance with the VCS rules.

For this assessment, the historic reference period is extended to include the original reference period and all subsequent monitoring periods up to the beginning of the current monitoring period. The fire reference period must not be extended, as this is a fixed 10-year period ending 5 years before the project start date.

The project proponent must, for the duration of the project, re-determine the PDT every 10 years. This reassessment must use the procedure provided in Section 5.1. Data sources for peat depths, depths of burn scars and subsidence rates must be updated if new information relevant to the project area has become available.

7 ADDITIONALITY

This methodology uses a project method for the demonstration of additionality.

Additionality must be determined using the latest version of the CDM tool *Combined tool to identify the baseline scenario and demonstrate additionality in A/R CDM project activities*, with additional guidance as provided in Section 6.1.

[10] Sub-step and footnotes as in version 01 of the tool, the prevailing version of the tool as of the writing of this methodology.

8 QUANTIFICATION OF GHG EMISSION REDUCTIONS AND REMOVALS

8.1 Baseline Emissions

8.1.1 General approach

The net CO_2 equivalent emissions in the baseline scenario may be determined by carbon stock changes in non-peat carbon pools, GHG emissions as a result of peat oxidation due to drainage, or a combination of these. In addition, emissions as a result of peat combustion due to peatland fires can be determined.

GHG emissions of non-forested areas are determined using GESTs (Section 8.1.3). For forested areas, emissions are determined using GESTs (covering peat, herb vegetation and litter) in combination with carbon stock changes of the above- and below-ground tree biomass (Section 8.1.2).

For areas for which the vegetation composition does not provide a clear indication of GHG emissions (bare peat, transient phases of vegetation development after rewetting) water table depth measurements must be used as additional input to assess GHG fluxes. However, project proponents may also opt to choose water table depth as a proxy for the entire project area.

Peat combustion due to anthropogenic peatland fires is addressed using a conservative default value (*Fire Reduction Premium*) that is expressed as a proportion of the CO_2 emissions avoided through rewetting (Section 8.3).

It must be demonstrated (e.g., by referring to peer-reviewed literature) that under the project scenario, N_2O emissions are insignificant or decrease in the project scenario compared to the baseline, and therefore N_2O emissions need not be accounted for. Project circumstances are defined by pre-project land use (e.g., forestry, peat mining, agriculture, abandonment after such activities) and its intensity (especially related to N-fertilization), climatic zone, water table depths, and peat type.

The net CO_2 equivalent emissions in the baseline are estimated as:

$$GHG_{BSL} = \sum_{t=1}^{t^*} \sum_{i=1}^{M_{BSL}} \left(-\frac{44}{12} \times \Delta C_{BSL-NP,i,t} + GHG_{drained,i,t} \right) \quad \textbf{(12)}$$

Where:

GHG_{BSL}	Net CO_2 equivalent emissions in the baseline scenario up to year t^*; t CO_2e
$\Delta C_{BSL-NP,i,t}$	Net carbon stock changes in non-peat carbon pools in the baseline scenario in stratum i in year t; t C yr^{-1}
$GHG_{drained,i,t}$	Greenhouse gas emissions from soil, lower ground vegetation and litter in the baseline scenario in stratum i in year t; t CO_2e yr^{-1}

i	1, 2, 3, … M_{BSL} strata in the baseline scenario
t	1, 2, 3, … t^* years elapsed since the project start

The project proponent must, for the duration of the project, re-quantify the baseline every 10 years. Based on the reassessment as defined in Section 6, the new baseline scenario must be incorporated into revised estimates of baseline emissions. This baseline reassessment must include the evaluation of the validity of proxies for GHG emissions from peatlands (i.e., GESTs on the basis of vegetation composition and/or water table depth).

8.1.2 Net carbon stock change in non-peat carbon pools ($\Delta C_{BSL\text{-}NP,i,t}$)

8.1.2.1 General

The non-peat carbon pools (see Table 5.1) to be accounted for in the baseline scenario include aboveground tree biomass and belowground tree biomass. Net fluxes to and from lower ground vegetation and litter are accounted for by GESTs.

GHG emissions may arise from the burning of biomass. Biomass burning in the baseline scenario may occur but not accounting for it is conservative. This methodology does not provide procedures for estimating GHG emissions from the burning of biomass.

Net carbon stock changes in non-peat carbon pools in the baseline scenario will be determined as:

$$\Delta C_{BSL\text{-}NP,i,t} = \Delta C_{BSL\text{-}biomass,i,t} \quad \textbf{(13)}$$

Where:

$\Delta C_{BSL\text{-}NP,i,t}$	Net carbon stock change in non-peat carbon pools in the baseline scenario in stratum i in year t; t C yr^{-1}
$\Delta C_{BSL\text{-}biomass,i,t}$	Net carbon stock change in tree biomass in the baseline scenario in stratum i in year t; t C yr^{-1}
i	1, 2, 3, … M_{BSL} strata in the baseline scenario
t	1, 2, 3, … t^* years elapsed since the project start

Assessing GHG removals in the baseline scenario consists of 3 steps:

1) Assess the pre-project spatial distribution of tree biomass
2) For the given baseline scenario, derive a time series of tree biomass development for each stratum; as per Section 6.2, *ex-ante* baseline projections beyond a 10-year period are not required
3) Determine annual GHG removals per stratum; as per Section 6.2, *ex-ante* baseline projections beyond a 10-year period are not required

To project future tree biomass within the project crediting period under the baseline scenario, use the latest version of the VCS module *VMD0019 Methods to Project Future Conditions*.

8.1.2.2 Net carbon stock change in biomass ($\Delta C_{BSLbiomass,i,t}$)

The net carbon stock change in biomass in the baseline scenario is estimated as:

$$\Delta C_{BSL\text{-}biomass,i,t} = A_{BSL,i,t} \times \Delta C_{BSL\text{-}tree,i,t} \quad (14)$$

$$\Delta C_{BSL-tree,i,t} = \sum_{j=1}^{S_{BSL}} (\Delta C_{BSL-tree,j,i,t}) \quad (15)$$

$$\Delta C_{BSL-tree,j,i,t} = \Delta C_{BSL-tree-AB,j,i,t} + \Delta C_{BSL-tree-BB,j,i,t} \quad (16)$$

$$\Delta C_{BSL-tree-BB,j,i,t} = \Delta C_{BSL-tree-AB,j,i,t} \times R_j \quad (17)$$

Where:

$\Delta C_{BSL\text{-}biomass,i,t}$	Change in carbon stock in biomass in the baseline scenario in stratum *i* in year *t*; t C yr^{-1}
$A_{BSL,i,t}$	Area of baseline stratum *i* in year *t*; ha
$\Delta C_{BSL\text{-}tree,i,t}$	Change in carbon stock in tree[11] biomass in the baseline scenario in stratum *i* in year *t*; t C $ha^{-1}yr^{-1}$
$\Delta C_{BSL\text{-}tree,j,i,t}$	Change in carbon stock in tree biomass in the baseline scenario for species *j* in stratum *i* in year *t*; t C $ha^{-1}yr^{-1}$
$\Delta C_{BSL\text{-}tree\text{-}AB,j,i,t}$	Change in carbon stock in above-ground tree biomass in the baseline scenario for species *j* in stratum *i* in year *t*; t C $ha^{-1}yr^{-1}$
$\Delta C_{BSL\text{-}tree\text{-}BB,j,i,t}$	Change in carbon stock in below-ground tree biomass in the baseline scenario for species *j* in stratum *i* in year *t*; t C $ha^{-1}yr^{-1}$
R_j	Root:shoot ratio for tree species *j*[12]; t root t^{-1} shoot d.m.
j	1, 2, 3, … S_{BSL} tree species in the baseline scenario
i	1, 2, 3, … M_{BSL} strata in the baseline scenario
t	1, 2, 3, … t^* years elapsed since the project start

Above-ground tree biomass

The change in carbon stock in above-ground tree biomass is estimated using one of the following methods that can be selected on the basis of the availability of data.

[11] With DBH ≥ 5 cm.
[12] Care should be taken that the root-shoot ratio may change as a function of the above-ground biomass present at time *t* (see IPCC GPG 2003, Annex 3.A1, Table 3A1.8)

Method 1 (Gain-loss method)

$$\Delta C_{BSL\text{-}tree\text{-}AB,j,i,t} = \Delta C_{G,j,i,t} - \Delta C_{L,j,i,t} \quad \textbf{(18)}$$

$$\Delta C_{G,j,i,t} = G_{j,i,t} \times CF_j \quad \textbf{(19)}$$

$$G_{j,i,t} = I_{v,j,i,t} \times D_j \times BEF_{1,j} \quad \textbf{(20)}$$

Where:

$\Delta C_{BSL\text{-}tree\text{-}AB,j,i,t}$	Change in carbon stock in above-ground tree biomass in the baseline scenario for species *j* in stratum *i* in year *t*; t C $ha^{-1}yr^{-1}$
$\Delta C_{G,j,i,t}$	Average annual increase in carbon stock due to above-ground biomass growth of living trees for species *j* in stratum *i* in year *t*; t C $ha^{-1}yr^{-1}$
$\Delta C_{L,j,i,t}$	Average annual decrease in carbon stock due to above-ground biomass loss of living trees for species *j* in stratum *i* in year *t*; t C $ha^{-1}yr^{-1}$
$G_{j,i,t}$	Average annual increment of above-ground biomass of living trees for species *j* in stratum *i* in year *t*; t dm. $ha^{-1}yr^{-1}$
CF_j	Carbon fraction[13] of dry matter for species *j*; t C t d.m.$^{-1}$
$I_{v,j,i,t}$	Average annual increment in merchantable volume for species *j* in stratum *i* in year *t*; $m^{-3}ha^{-1}yr^{-1}$
D_j	Basic wood density for species *j*; t d.m. m^{-3}
$BEF_{1,j}$	Biomass expansion factor for conversion of annual net increment (including bark) in merchantable volume to total above-ground biomass increment for species *j*
j	1, 2, 3, … *S* tree species
i	1, 2, 3, … M_{BSL} strata in the baseline scenario
t	1, 2, 3, … t^* years elapsed since the project start

This methodology allows for the conservative assumption that, for any time *t,* $\Delta C_{L,j,i,t} = 0$ for the baseline scenario.

If biomass increment tables are available and applicable to the species present, these can directly be used in Equation 20. Note that available data on average annual increment in the volume of species *j* in stratum *i* for year *t* ($I_{v,j,i,t}$) may be expressed as a net average annual increment (i.e., the term $\Delta C_{L,j,i,t}$ is already implicitly allowed for and must be set to zero in Equation 18 in order to avoid double counting).

Alternatively, if the average annual increment in volume of species *j* in stratum *i*, for year *t* ($I_{v,j,i,t}$) is expressed as the gross average annual increment, then $\Delta C_{L,j,i,t}$ may be conservatively assumed

[13] IPCC default value = 0.5

as zero. Otherwise $\Delta C_{L,j,i,t}$ must be estimated on the basis of transparent and verifiable information on the rate at which pre-project activities (or mortality) are reducing carbon stocks in existing live trees (e.g., due to harvesting for fuelwood, or for animal consumption).

Depending on the kind of information locally available, instead of R_j and BEF_j one can use other parameters converting stem volume to total biomass, for example K_{ph} (Alexeyev coefficient; Alexeyev *et al*. (1995)).

Method 2 (Stock difference method)

$$\Delta C_{BSL\text{-}tree\text{-}AB,j,i,t} = (C_{BSL\text{-}tree\text{-}AB,j,i,t} - C_{BSL\text{-}tree\text{-}AB,j,i,(t\text{-}T)}) / T \quad \textbf{(21)}$$

Two methods are provided for this method: the biomass expansion factors (*BEF*) method and the allometric equations method.

1. *BEF* method

$$C_{BSL\text{-}tree\text{-}AB,j,i,t} = V_{j,i,t} \times D_j \times BEF_{2j} \times CF_j \quad \textbf{(22)}$$

Where:

$\Delta C_{BSL\text{-}tree\text{-}AB,j,i,t}$	Change in carbon stock in above-ground tree biomass in the baseline for species *j* in stratum *i* in year *t*; t C $ha^{-1}yr^{-1}$
$C_{BSL\text{-}tree\text{-}AB,j,i,t}$	Carbon stock in above-ground biomass of tree species *j* in stratum *i* in year *t*; t C ha^{-1}
$V_{j,i,t}$	Stem volume of tree species *j* in stratum *i* in year *t*; m^3 ha^{-1}
D_j	Basic wood density of species *j*; t d.m. m^{-3}
BEF_{2j}	Biomass expansion factor for conversion of stem biomass to above-ground tree biomass for species *j*
CF_j	Carbon fraction[14] of dry matter for species *j*; t C t $d.m.^{-1}$
i	1, 2, 3, … M_{WPS} strata in the project scenario
j	1, 2, 3 ,… S_{WPS} tree species in the project scenario
t	1, 2, 3 … t^* years elapsed since the start of the project activity
T	Number of years between times *t* and t_{-1}

[14] IPCC default = 0.5

2. Allometric Equations method

$$C_{BSL\text{-}tree\text{-}AB,j,i,t} = nTR_{j,i,t} \times f_j(X,Y,\ldots) \times CF_j \quad \textbf{(23)}$$

Where:

$C_{BSL\text{-}tree\text{-}AB,j,i,t}$	Carbon stock in above-ground biomass of species *j* in stratum *i* in year *t*; t C ha^{-1}
$nTR_{j,i,t}$	Tree stand density of species *j* in stratum *i* in year *t*; trees ha^{-1}
$f_j(X, Y, \ldots)$	Allometric equation for species *j* linking measured tree dimension variables (e.g., diameter at breast height (*DBH*) and possibly height (*H*)) to above-ground biomass of living trees; t d.m. tree^{-1}
CF_j	Carbon fraction of dry matter for species *j*; t C t^{-1} d.m.
i	1, 2, 3, … M_P strata in the project scenario
j	1, 2, 3, … S_{WPS} tree species in the project scenario
t	1, 2, 3, … *t** years elapsed since the start of the project activity

It is acceptable to estimate initial stocks (*t*=0) using pre-existing forest inventory data, provided that the pre-existing data (1) represents the project strata, (2) is not more than 10 years old and represents the age and site class, and (3) that the stock estimate derived from the pre-existing data has been validated with limited sampling within the project area. If the estimate is within the 90% confidence interval of the corresponding estimate calculated from pre-existing forest inventory data, the initial stock at *t*=0 is set at the higher bound of the 90% confidence interval of the estimate from pre-existing data. If the validation estimate is outside (i.e., greater than or less than) the corresponding estimate calculated from pre-existing forest inventory data, the estimate from pre-existing data cannot be used.

8.1.3 Greenhouse gas emissions due to peat drainage ($GHG_{drained,i,t}$)

8.1.3.1 The GEST approach

In this methodology, the GEST (Greenhouse Gas Emission Site Type) approach forms the basis for the estimation of GHG fluxes from drained and rewetted peatlands (Couwenberg *et al.* 2011). The GEST approach uses primarily vegetation types as the indicator of annual greenhouse gas fluxes. Vegetation is well qualified for indicating greenhouse gas fluxes (Couwenberg *et al.* 2011) as outlined in Section 9.3.6.

GHG emissions from drained peat, litter and ground vegetation are estimated based on the presence of GESTs with calibrated GHG emission profiles in strata *i*. As a general rule:

- for a non-forested area a GEST will determine average annual net CO_2 equivalent emissions
- for a forested area a GEST in combination with carbon stock changes in tree biomass will

determine average annual net CO_2 equivalent emissions.

In addition, for GESTs in which the vegetation composition does not provide a clear indication of GHG emission-related site conditions (e.g., bare peat), water table depth measurements must be used as additional input to assess GHG fluxes. Areas within the project boundary with different GESTs will be treated as different strata.

For each stratum:

$$GHG_{drained,i,t} = GHG_{GESTbsl,i,t} \quad \textbf{(24)}$$

$$\text{For } t > t_{PDT\text{-}BSL,i}: GHG_{drained,i,t} = 0 \quad \textbf{(25)}$$

Where:

$GHG_{drained,i,t}$	Greenhouse gas emissions from soil, lower ground vegetation and litter in the baseline scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
$t_{PDT\text{-}BSL,i}$	PDT in the baseline scenario in stratum *i* in years elapsed since the project start; yr
$GHG_{GESTbsl,i,t}$	GHG emissions from GESTs in the baseline scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
i	1, 2, 3, … M_{BSL} strata in the baseline scenario
t	1, 2, 3, … *t** years elapsed since the project start

Assessing GHG emissions in the baseline scenario consists of 4 steps (see Section 9.3.6 for additional guidance on each of these steps):

1) Determine GESTs
2) Assess the pre-project spatial distribution of GESTs
3) For the given baseline scenario, derive a time series of GEST development for each stratum; as per Section 6.2, *ex-ante* baseline projections beyond a 10-year period are not required
4) Determine annual GHG emissions per stratum; as per Section 6.2, *ex-ante* baseline projections beyond a 10-year period are not required

To project future GHG emissions due to peat drainage within the project crediting period under the baseline scenario, use the latest version of the VCS module *VMD0019 Methods to Project Future Conditions*, with the following additional guidance.

1. To derive trends and developments in water table management, the baseline scenario must take into account the current and historic layout of the drainage system and the long-term average climate variables influencing water table depths (precipitation, evaporation) prior to project start, on the basis of quantitative hydrological modeling and/or expert judgment. The long-

term average climate variables must be determined using data from two climate stations nearest to the project area and must include at least 20 years' worth of data.

The drainage layout at the start of the project activity must be mapped at scale: 1:10,000 or any other scale justified for estimating water table depths. Historic drainage layout must be mapped using topographic and/or hydrological maps from (if available) the start of the major hydrological impacts but covering at least the 20 years prior to the start of the project activity. Historic drainage structures (collapsed ditches) may (still) have higher hydraulic conductivity than the surrounding areas and function as preferential flow paths. The effect of historic drainage structures on current hydrological functioning of the project area must be assessed on the basis of expert judgment and in a conservative manner. Justification may be based on hydrological models. The baseline scenario may furthermore include re-activation of collapsed ditches. Historic information on the drainage system may serve to set trends in drainage lay-out and depth as well as in frequency of dredging of ditches to maintain required water tables in the field. Derivation of such trends must be done on the basis of expert judgment and in a conservative manner. With respect to hydrological functioning, baseline scenarios must be restricted by climate variables and quantify any impacts on the hydrological functioning as caused by planned measures outside the project area (such as dam construction or groundwater extraction), by demonstrating a hydrological connection to the planned measures (e.g., through ground water carrying soil layers).

2. In case of abandonment of pre-project land use in the baseline scenario, the baseline scenario must also consider - based on expert judgment taking account of verifiable local experience and/or studies and/or scientific literature and in a conservative way - non-human induced rewetting brought about by collapsing dikes or ditches that would have naturally closed over time, and progressive subsidence, leading to raising relative water levels, increasingly thinner aerobic layers and reduced CO_2 emission rates. Unless alternative evidence is provided, annual subsidence (as derived from subsidence - water table observations or models) must be assumed to result in a 1:1 proportional rise the water table relative to the surface in the area between ditches.

In case of continued or re-instated utilization and associated drainage, it must be demonstrated that ditch water tables are controlled (e.g., by weirs and periodic deepening (dredging) of ditches to maintain the water table between ditches at the required level). Documentation may include official plans, but also personal communication with local farmers and historic trends.

Water tables in the baseline may be determined by static (including analytic) hydrologic modeling, using conservative peat hydraulic parameters, including:

- The distance between the ditches
- The water table depth in the ditches
- Hydrological conductivity of the peat

Based on the assessment of changes in water table depth, time series of vegetation composition must be derived (*ex ante*), based on vegetation succession schemes in drained peatlands from scientific literature and/or expert judgment, by defining time series of GESTs, with time steps of, for example, 5 years to allow for the inherent discrete character of the GESTs.

If a *Fire Reduction Premium* is claimed, the project proponent must demonstrate with fire maps and historical databases on fires that the project area is now and in future would be under risk of anthropogenic fires. This is further specified in Section 8.3.

8.1.3.2 Baseline CO_2 and CH_4 emissions estimated by GEST

GHG emissions per stratum as a result of peat drainage (microbial peat oxidation, net fluxes to and from litter and lower ground vegetation) in the baseline scenario are estimated as:

$$GHG_{GESTbsl,i,t} = A_{BSl,i,t} \times (GHG_{GESTbsl\text{-}CO2,i,t} + GHG_{GESTbsl\text{-}CH4,i,t}) \quad \textbf{(26)}$$

Where:

$GHG_{GESTbsl,i,t}$	GHG emissions from GEST in the baseline scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
$A_{BSL,i,t}$	Total area of baseline stratum *i* in year *t*; ha
$GHG_{GESTbsl\text{-}CO2,i,t}$	Emission of CO_2 from baseline GEST in stratum *i* in year *t*; t CO_2e $ha^{-1}yr^{-1}$
$GHG_{GESTbsl\text{-}CH4,i,t}$	Emission of CH_4 from baseline GEST in stratum *i* in year *t*; t CO_2e $ha^{-1}yr^{-1}$
i	1, 2, 3 …M_{BSL} strata[15] in the baseline scenario
t	1, 2, 3, … *t** years elapsed since the project start

If the vegetation composition does not provide a clear indication of GHG emission-related site conditions (e.g., bare peat) the average annual GHG emissions must be related directly to water table depth as follows:

$$GHG_{GESTbsl,i,t} = A_{BSL,i,t} \times (GHG_{WLbsl\text{-}CO2,i,t} + GHG_{WLbsl\text{-}CH4,i,t}) \quad \textbf{(27)}$$

Where:

$GHG_{GESTbsl,i,t}$	GHG emissions from GEST in the baseline scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
$A_{BSL,i,t}$	Total area of baseline stratum *i* in year *t*; ha
$GHG_{WLbsl\text{-}CO2,i,t}$	Emission of CO_2 related to water table depth in the baseline scenario in stratum *i* in year *t*; t CO_2e $ha^{-1}yr^{-1}$
$GHG_{WLbsl\text{-}CH4,i,t}$	Emission of CH_4 related to water table depth in the baseline scenario in stratum *i* in year *t*; t CO_2e $ha^{-1}yr^{-1}$
i	1, 2, 3, … M_{BSL} strata[16] in the baseline scenario

[15] Note that different GESTs result in different strata.

t 1, 2, 3, … t* years elapsed since the project start

The project may establish project-specific values for $GHG_{WLbsl\text{-}CO2}$ and $GHG_{WLbsl\text{-}CH4}$ (see Section 9.3.6) or apply values from appropriate literature sources pertaining to land use classes, water table depths or water table depth classes and similar project circumstances. For such literature values the accuracy must be defined or conservativeness must be justified in the project description. Project circumstances are defined by pre-project land use (e.g., forestry, peat mining, agriculture, abandonment after such activities) and its intensity, climatic zone, water table depths, and peat type. If the mean annual water table depth in the project area exceeds the depth range for which the emission-vegetation or emission-water table depth relationship determined for the project is valid, a conservative extrapolation must be used. $GHG_{WLbsl\text{-}CH4}$ may be conservatively neglected.

Procedures for the determinations of GHG fluxes and water table depth measurements are provided in Section 9.3.6.

8.2 Project Emissions

8.2.1 General approach

The net CO_2 equivalent emissions in the project scenario may be determined by carbon stock changes in non-peat carbon pools and GHG emissions from rewetted peatland.

GHG emissions from fossil fuel combustion from transport and machinery use in project activities are deemed insignificant.

For the quantification of possible spikes of CH_4 emission during a transient period after rewetting, for which the GEST approach cannot be used, conservative estimates from appropriate literature sources are used.

To demonstrate that N_2O emissions are a) insignificant or b) decrease compared to the baseline scenario, and therefore N_2O emissions need not be accounted for, a) use the CDM A/R methodological tool *Tool for testing significance of GHG emissions in A/R CDM project activities*, or b) refer to peer-reviewed literature, respectively.

For *ex-ante* estimates of GHG emissions in the project scenario use the latest version of the VCS module *VMD0019 Methods to Project Future Conditions*.

The net CO_2 equivalent emissions in the project scenario are estimated as:

---

[16] Note that different water levels or water level classes result in different strata. Water levels or water level classes (e.g., 0-10 cm, 11-20 cm, etc.) can be used, depending on data availability.

$$GHG_{WPS} = \sum_{t=1}^{t^*} \sum_{i=1}^{M_{WPS}} \left(-\frac{44}{12} \times \Delta C_{WPS-NP,i,t} + GHG_{rewetted,i,t} \right) \quad (28)$$

Where:

GHG_{WPS}	Net CO_2 equivalent emissions in the project scenario up to year t^*; t CO_2e
$\Delta C_{WPS\text{-}NP,i,t}$	Net carbon stock change in non-peat carbon pools in the project scenario in stratum i in year t; t C yr^{-1}
$GHG_{rewetted,i,t}$	Greenhouse gas emissions from the peat after rewetting in the project scenario in stratum i in year t; t CO_2e yr^{-1}
i	1, 2, 3, … M_{BSL} strata in the project scenario
t	1, 2, 3, … t^* years elapsed since the project start

8.2.2 Net carbon stock changes in non-peat carbon pools ($\Delta C_{WPS\text{-}NP,i,t}$)

Under the applicability conditions, the burning of biomass is excluded in the project scenario. This methodology does not provide procedures for estimating GHG emissions from the burning of biomass.

Monitoring procedures for carbon stocks in tree biomass in the project scenario are provided in Section 9.

Net carbon stock changes in non-peat carbon pools in the project scenario will be determined as:

$$\Delta C_{WPS\text{-}NP,i,t} = \Delta C_{WPS\text{-}biomass,i,t} \quad (29)$$

Where:

$\Delta C_{WPS\text{-}NP,i,t}$	Net carbon stock change in non-peat carbon pools in the project scenario in stratum i in year t; t C yr^{-1}
$\Delta C_{WPS\text{-}biomass,i,t}$	Net carbon stock change in tree biomass in the project scenario in stratum i in year t; t C yr^{-1}
i	1, 2, 3, … M_{BSL} strata in the baseline scenario
t	1, 2, 3, … t^* years elapsed since the project start

$$\Delta C_{WPS\text{-}Biomass,i,t} = A_{WPS,i,t} \times \Delta C_{WPS\text{-}tree,i,t} \quad (30)$$

$$\Delta C_{WPS-tree,i,t} = \sum_{j=1}^{S_{WPS}} \left(\Delta C_{WPS-tree,j,i,t} \right) \quad (31)$$

$$\Delta C_{WPS-tree,j,i,t} = \Delta C_{WPS-tree-AB,j,i,t} + \Delta C_{WPS-tree-BB,j,i,t} \quad (32)$$

$$\Delta C_{WPS-tree-BB,j,i,t} = \Delta C_{WPS-tree-AB,j,i,t} \times R_j \quad \textbf{(33)}$$

Where:

$\Delta C_{WPS\text{-}biomass,i,t}$	Change in carbon stock in biomass in the project scenario in stratum *i* in year *t*; t C yr^{-1}
$A_{WPS,i,t}$	Area of project stratum *i* in year *t*; ha
$\Delta C_{WPS\text{-}tree,i,t}$	Change in carbon stock in tree[17] biomass in the project scenario in stratum *i* in year *t*; t C $ha^{-1}yr^{-1}$
$\Delta C_{WPS\text{-}tree,j,i,t}$	Change in carbon stock in tree biomass in the project scenario for species *j* in stratum *i* in year *t*; t C $ha^{-1}yr^{-1}$
$\Delta C_{WPS\text{-}tree\text{-}AB,j,i,t}$	Change in carbon stock in above-ground tree biomass in the project scenario for species *j* in stratum *i* in year *t*; t C $ha^{-1}yr^{-1}$
$\Delta C_{WPS\text{-}tree\text{-}BB,j,i,t}$	Change in carbon stock in below-ground tree biomass in the project scenario for species *j* in stratum *i* in year *t*; t C $ha^{-1}yr^{-1}$
R_j	Root:shoot ratio for tree species *j*; t root t^{-1} shoot d.m.
j	1, 2, 3, … S_{WPS} tree species in the project scenario
i	1, 2, 3, … M_{WPS} strata in the project scenario
t	1, 2, 3, … t^* years elapsed since the project start

Changes in carbon stock in above-ground tree biomass in the project scenario are estimated as:

$$\Delta C_{WPS\text{-}tree\text{-}AB,j,i,t} = (C_{WPS\text{-}tree\text{-}AB,j,i,t} - C_{WPS\text{-}tree\text{-}AB,j,i,(t-T)}) / T \quad \textbf{(34)}$$

Where:

$\Delta C_{WPS\text{-}tree\text{-}AB,j,i,t}$	Net carbon stock change in above-ground tree biomass in the project scenario for tree species *j* in stratum *i* in year *t*; t C $ha^{-1}yr^{-1}$
$C_{WPS\text{-}tree\text{-}AB,j,i,t}$	Carbon stock in above-ground tree biomass in the project scenario for tree species *j* in stratum *i* in year *t*; t C ha^{-1}[18]
t	1, 2, 3 … ***t**** years elapsed since the start of the project activity
i	1, 2, 3, … M_{WPS} strata in the project scenario
j	1, 2, 3, … S_{WPS} tree species
T	Number of years between monitoring times t_m *and* t_{m-1}

The mean carbon stock in above-ground biomass per unit area is estimated on the basis of field

[17] With DBH ≥ 5 cm.
[18] May be conservatively set to zero.

measurements in permanent sample plots. Two methods are available: the biomass expansion factors (*BEF*) method and the allometric equations method.

1) *BEF* method

Step 1: Determine on the basis of available data volume tables (*ex ante*) and measurements (*ex post*) of the diameter at breast height (*DBH,* at typically 1.3 m above-ground level), and also preferably height (*H*), of all the trees above some minimum *DBH* in the permanent sample plots. The exact tree dimensions to be measured will be specified by the information obtained in Step 2.

Step 2: Estimate the stem volume of trees

It is possible to combine Steps 1 and 2 if volume tables allow for deriving average volume of trees, or field instruments (e.g., a relascope) that measure the volume of each tree directly are applied.

Step 3: Choose *BEF*

Step 4: Convert the stem volume of trees into carbon stock in above-ground tree biomass via basic wood density, the *BEF* and the carbon fraction:

$$C_{WPS\text{-}tree\text{-}AB,l,j,i,sp,t} = V_{l,j,i,sp,t} \times D_j \times BEF_{2j} \times CF_j \qquad \textbf{(35)}$$

Where:

$C_{WPS\text{-}tree\text{-}AB,l,j,i,sp,t}$	Carbon stock in above-ground biomass of tree *l* of species *j* in plot *sp* in stratum *i* in year *t*; t C tree^{-1}
$V_{l,j,j,sp,t}$	Stem volume of tree *l* of species *j* in plot *sp* in stratum *i* in year *t*; m^3 tree^{-1}
D_j	Basic wood density of species *j*; t d.m. m^{-3}
BEF_{2j}	Biomass expansion factor for conversion of stem biomass to above-ground tree biomass for species *j*
CF_j	Carbon fraction[19] of dry matter for species *j*; t C t d.m.$^{-1}$
l	1, 2, 3, … $N_{j,i,sp,t}$ individual trees of species *j* in sample plot *sp* in stratum *i* in year *t*
i	1, 2, 3, … M_{WPS} strata in the project scenario
j	1, 2, 3, … S_{WPS} tree species in the project scenario
t	1, 2, 3, … *t** years elapsed since the start of the project activity

Step 5: Calculate carbon stock in above-ground biomass of all tree species *j* present in plot *sp* in stratum *i* at time *t* (i.e., summation over all trees *l* of species *j* present in plot *sp*).

[19] IPCC default = 0.5

$$C_{WPS-tree-AB,j,i,sp,t} = \sum_{l=1}^{N_{j,i,sp,t}} C_{WPS-tree-AB,l,j,i,sp,t} \quad (36)$$

Where:

$C_{WPS\text{-}tree\text{-}AB,j,i,sp,t}$	Carbon stock in above-ground biomass of tree species *j* on plot *sp* of stratum *i* at time *t*; t C
$C_{WPS\text{-}tree\text{-}AB,l,j,i,sp,t}$	Carbon stock in above-ground biomass of tree *l* of species *j* in plot *sp* in stratum *i* at time *t*; t C tree^{-1}
l	1, 2, 3, … $N_{j,i,sp,t}$ individual trees of species *j* in sample plot *sp* in stratum *i* in year *t*
i	1, 2, 3, … M_{WPS} strata in the project scenario
j	1, 2, 3, … S_{WPS} tree species in the project scenario
sp	1, 2, 3, … P_i sample plots in stratum *i* in the project scenario
t	1, 2, 3, … t^* years elapsed since the start of the project activity

Step 6: Estimate the mean carbon stock in above-ground tree biomass for species *j* for each stratum:

$$C_{WPS-tree-AB,j,i,t} = \frac{1}{A_{sp_i}} \sum_{sp=1}^{P_i} C_{WPS-tree-AB,j,i,sp,t} \quad (37)$$

Where:

$C_{WPS\text{-}tree\text{-}AB,j,i,t}$	Above-ground carbon stock in tree species *j* in stratum *i* in year *t*; t C ha^{-1}
$C_{WPS\text{-}tree\text{-}AB,j,i,sp,t}$	Above-ground carbon stock in tree species *j* on plot *sp* of stratum *i* in year *t*; t C
$A_{sp,i}$	Total area of all sample plots in stratum *i*; ha
j	1, 2, 3, … S_{WPS} tree species in the project scenario
i	1, 2, 3, … M_{WPS} strata in the project scenario
sp	1, 2, 3, … P_i sample plots in stratum *i* in the project scenario
t	1, 2, 3, … t^* years elapsed since the start of the project activity

The below-ground tree biomass in the project scenario may be conservatively set to zero. Procedures for including below-ground biomass in total tree biomass estimations are provided in Section 8.1.2.

2) Allometric equations method

Step 1: Same as Step 1 of the *BEF* method.

Step 2: Select or develop an appropriate allometric equation (if possible species-specific, or if not from a similar species) - see Chapter 9 for additional guidance.

Step 3: Estimate carbon stock in above-ground biomass for each individual tree *l* of species *j* in the sample plot *sp* located in stratum *i* using the selected or developed allometric equation applied to the tree dimensions resulting from Step 1, and sum the carbon stocks in the sample plot:

$$C_{WPS-tree-AB,j,i,sp,t} = \sum_{l=1}^{N_{j,i,sp,t}} \left(f_j(X,Y,...)\right) \times CF_j \tag{38}$$

Where:

$C_{WPS\text{-}tree\text{-}AB,j,i,sp,t}$	Carbon stock in above-ground biomass of tree species *j* in sample plot *sp* in stratum *i* in year *t*; t C
$f_j(X, Y, \ldots)$	Allometric equation for species *j* linking measured tree dimension variables (e.g., diameter at breast height (*DBH*) and possibly height (*H*)) to above-ground biomass of living trees; t d.m. tree^{-1}
CF_j	Carbon fraction of dry matter for species *j*; t C t^{-1} d.m.
l	1, 2, 3, … $N_{j,i,sp,t}$ individual trees of species *j* in sample plot *sp* in stratum *i* in year *t*
j	1, 2, 3, … S_{WPS} tree species in the project scenario
i	1, 2, 3, … M_P strata in the project scenario
sp	1, 2, 3, … P_i sample plots in stratum *i* in the project scenario
t	1, 2, 3, … t^* years elapsed since the start of the project activity

Step 4: Proceed with Step 6 of the *BEF* method.

8.2.3 Project greenhouse gas emissions after peat rewetting ($GHG_{rewetted,i,t}$)

The estimation of GHG emissions in rewetted peat follows similar procedures as provided in Section 8.1.3.

For each stratum:

$$GHG_{rewetted,i,t} = GHG_{GESTwps,i,t} \tag{39}$$

Where:

$GHG_{rewetted,i,t}$	Greenhouse gas emissions from soil, lower ground vegetation and litter in the project scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
$GHG_{GESTwps,i,t}$	GHG emissions from GESTs in the project scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
i	1, 2, 3, …M_{BSL} strata in the project scenario
t	1, 2, 3, … *t** years elapsed since the project start

8.2.3.1 Project GHG emissions related to GESTs

This approach builds on the procedure described in Section 8.1.3.1. In addition, the GHG emissions during the transient stage after rewetting (i.e., before new vegetation types have established that are in balance with the rewetted conditions and for from which GESTs can be defined) must be determined.

The GEST approach for the project scenario has the following steps (see Section 9.3.6 for additional guidance on each of these steps):

1) Determine GESTs
2) Assess the spatial distribution of GESTs
3) Define the project scenario for GESTs (*ex ante*) or monitor GESTs (*ex post*)
4) Determine annual GHG emissions per stratum for the entire project crediting period

For the quantification of possible spikes of CH_4 emission during a transient period after rewetting where dying off vegetation may lead to substantial methane emissions, for which the GEST approach cannot be used, conservative estimates from appropriate literature sources must be used. The project proponent must demonstrate applicability of that literature on the basis of similarity with respect to pre-project land use (e.g., forestry, peat mining, agriculture) and land use intensity (especially fertilization), superficial peat types (especially nutrient conditions), and climatic zone.

GHG emissions per stratum of peat after rewetting are estimated as:

$$GHG_{rewetted,i,t} = A_{WPS,i,t} \times (GHG_{GESTwps\text{-}CO2,i,t} + GHG_{GESTwps\text{-}CH4,i,t}) \quad \textbf{(40)}$$

Where:

$GHG_{rewetted,i,t}$	Greenhouse gas emissions from soil, lower ground vegetation and litter in the project scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
$A_{WPS,i,t}$	Total area of project stratum *i*; ha
$GHG_{GESTwps\text{-}CO2,i,t}$	Emission of CO_2 from project GEST in stratum *i* in year *t*; t CO_2e $ha^{-1}yr^{-1}$

$GHG_{GESTwps\text{-}CH4,i,t}$	Emission of CH_4 from project GEST in stratum *i* in year *t*; t CO_2e $ha^{-1}yr^{-1}$
i	1, 2, 3, …M_{BSL} strata in the project scenario
t	1, 2, 3, … *t** years elapsed since the project start

Ex-ante estimates of $GHG_{rewetted,i,t}$ must be based on *ex-ante* scenario definitions in Step 3.

Ex-post estimates of $GHG_{rewetted,i,t}$ must be based on monitoring results.

If the vegetation composition does not provide a clear indication of GHG emission-related site conditions (e.g., bare peat, transient phases of vegetation development after rewetting) the average annual GHG emissions must be related directly to water table depth. Note that due to a potential hysteresis effect the relationships between water table depth and greenhouse gas emissions in a rewetted peatland can differ from those in a drained peatland.

$$GHG_{GESTwps,i,t} = A_{WPS,i,t} \times (GHG_{WL\text{-}CO2,i,t} + GHG_{WL\text{-}CH4,i,t}) \quad \textbf{(41)}$$

Where:

$GHG_{GESTwps,i,t}$	GHG emissions from GESTs in the project scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
$A_{WPS,i,t}$	Total area of project stratum *i* in year *t*; ha
$GHG_{WLwps\text{-}CO2,i,t}$	Emission of CO_2 related to water table depth in the project scenario in stratum *i* in year *t*; t CO_2e $ha^{-1}yr^{-1}$
$GHG_{WLwps\text{-}CH4,i,t}$	Emission of CH_4 related to water table depth in the project scenario in stratum *i* in year *t*; t CO_2e $ha^{-1}yr^{-1}$
i	1, 2, 3, …M_{BSL} strata[20] in the project scenario
t	1, 2, 3, … *t** years elapsed since the project start

The project may establish project-specific values for $GHG_{WLwps\text{-}CO2}$ and $GHG_{WLwps\text{-}CH4}$ or apply values from appropriate literature sources pertaining to land use classes, water table depths or water table depth classes. For such literature values the accuracy must be defined or conservativeness must be justified. If the mean annual water table depth in the project area exceeds the depth range for which the emission-vegetation or emission-water table depth relationship determined for the project is valid, a conservative extrapolation must be used.

Procedures for the determinations of GHG fluxes and water table depth measurements are provided in Section 9.3.6.

[20] Note that different water levels or water level classes result in different strata. Water levels or water level classes (e.g., 0-10 cm, 11-20 cm, etc.) can be used, depending on data availability

8.2.3.2 Direct estimate approach

GEST conversion assessments may provide direct conservative estimates of emission reductions due to rewetting, rather than providing estimates of baseline and project emissions separately (e.g., a conversion of GEST type a to type b is associated with a given emission reduction with a given uncertainty, or the emission reduction is estimated conservatively).

Table 8.1. Suggested table format for conservative estimates of emission reductions for GEST conversions from drained to rewetted.

Table 8.1: Estimated Emission Reductions for GEST Conversions

GEST t_1	GEST t_2	Emission reduction t CO_2e $ha^{-1}yr^{-1}$
…	…	…
…	…	…

Where this approach is applied, equation 55 in Section 8.5 is amended to:

$$NER_{RDP} = 44/12 \times (\Delta C_{BSL} - \Delta C_{WPS}) + \Delta GHG_{rewetting} + \mathit{Fire\ Reduction\ Premium} - GHG_{LK} \quad \textbf{(42)}$$

The greenhouse gas emission reduction due to rewetting is estimated as:

$$\Delta GHG_{rewetting,i,t} = A_{i,t} \times ((GHG_{GESTbsl\text{-}CO2,i,t} + GHG_{GESTbsl\text{-}CH4,i,t}) - (GHG_{GESTwps\text{-}CO2,i,t} + GHG_{GESTwps\text{-}CH4,i,t})) \quad \textbf{(43)}$$

Where:

$\Delta GHG_{rewetting,i,t}$	Greenhouse gas emission reduction due to rewetting in stratum *i* in year *t*; t CO_2e yr^{-1}
$A_{i,t}$	Total area of stratum *i* in year *t*[21];; ha
$GHG_{GESTbsl\text{-}CO2,i,t}$	Emission of CO_2 from baseline GEST in stratum *i* in year *t*; t CO_2e $ha^{-1}yr^{-1}$
$GHG_{GESTwps\text{-}CO2,i,t}$	Emission of CO_2 from project GEST in stratum *i* in year *t*; t CO_2e $ha^{-1}yr^{-1}$
$GHG_{GESTbsl\text{-}CH4,i,t}$	Emission of CH_4 from baseline GEST in stratum *i* in year *t*; t CO_2e $ha^{-1}yr^{-1}$
$GHG_{GESTwps\text{-}CH4,i,t}$	Emission of CH_4 from project GEST in stratum *i* in year *t*; t CO_2e $ha^{-1}yr^{-1}$
i	1, 2, 3, … M_{BSL} strata in the project scenario
t	1, 2, 3, … *t** years elapsed since the project start

[21] Note that if baseline strata are subdivided in the project scenario, areas $A_{i,t}$ are equal to $A_{WPS,i,t}$ of the relevant strata *i*; if baseline strata are merged in the project scenario, areas $A_{i,t}$ are equal $A_{WPS,i,t}$ of strata that include the merged baseline strata *i*. For unaffected strata $A_{i,t}$ equals $A_{WPS,i,t}$

$$\Delta GHG_{rewetting} = \sum_{t=1}^{t^*} \sum_{i=1}^{M_{WPS}} \Delta GHG_{rewetting,i,t} \tag{44}$$

For $t > t_{PDT\text{-}BSL,i}$:

$$GHG_{rewetting,i,t} = 0 \tag{45}$$

Where:

$\Delta GHG_{rewetting}$	Greenhouse gas emission reduction due to rewetting up to year t^*; t CO_2e
$GHG_{rewetting,i,t}$	Greenhouse gas emission reduction due to rewetting in stratum i in year t; t CO_2e yr^{-1}
Fire Reduction Premium	Greenhouse gas emission reduction from peat combustion due to rewetting and fire management up to year t^*; t CO_2e
GHG_{LK}	Net CO_2 equivalent emissions in the project scenario due to leakage up to year t^*; t CO_2e
$t_{PDT\text{-}BSL,i}$	PDT in the baseline scenario in stratum i in years elapsed since the project start; yr
i	1, 2, 3, … M_{BSL} strata in the baseline scenario
t	1, 2, 3, … t^* years elapsed since the project start

$$\Delta C_{BSL} = \sum_{t=1}^{t^*} \sum_{i=1}^{M_{BSL}} \Delta C_{BSL-NP,i,t} \tag{46}$$

Where:

ΔC_{BSL}	Net carbon stock change in non-peat carbon pools in the baseline scenario up to year t^*; t CO_2e
$\Delta C_{BSL\text{-}NP,i,t}$	Net carbon stock change in non-peat carbon pools in the baseline scenario in stratum i in year t; t CO_2e yr^{-1}
i	1, 2, 3, … M_{BSL} strata in the baseline scenario
t	1, 2, 3, … t^* years elapsed since the project start

$$\Delta C_{WPS} = \sum_{t=1}^{t^*} \sum_{i=1}^{M_{BSL}} \Delta C_{WPS-NP,i,t} \tag{47}$$

Where:

ΔC_{WPS}	Net carbon stock change in non-peat carbon pools in the project scenario up to year t^*; t CO_2e

$\Delta C_{WPS\text{-}NP,i,t}$	Net carbon stock change in non-peat carbon pools in the project scenario in stratum *i* in year *t*; t CO_2e yr^{-1}
i	1, 2, 3, … M_{WPS} strata in the project scenario
t	1, 2, 3, … *t** years elapsed since the project start

8.3 Fire Reduction Premium

This methodology addresses anthropogenic peat fires occurring in drained peatland and establishes a conservative default value, based on fire occurrence and extension in the project area in the baseline scenario, so as to avoid the direct assessment of GHG emissions from fire in the baseline and the project scenarios.

The *Fire Reduction Premium* approach is only applicable if anthropogenic peat fires do not occur in the project scenario. The use of fire as a management tool (non-catastrophic fires or human-induced fires) in the project scenario is not allowed in the case that the *Fire Reduction Premium* approach is used to estimate emissions from peat fire.

The 20% Fire Reduction Premium

The 20% fire reduction premium is a rapid and conservative approach to acknowledging fire emission reductions as a result of rewetting without having to develop complex baseline scenarios for peat fires. Emissions from peat fires are, like emissions from microbial peat oxidation, negatively correlated with water table depth (cf. Turetsky *et al*., 2011, Ballhorn *et al.*, 2009). This allows a correlation of emissions from peat fires and microbial peat oxidation. Carbon losses from peat fires[22] are per hectare burned area on average ~10 times larger than the annual carbon emissions from microbial peat oxidation per ha drained peatland (i.e., in temperate and boreal areas; in tropical SE Asia even ~20 times, cf. Ballhorn *et al.*, 2009, Couwenberg *et al.*, 2010, Van der Werf *et al.*, 2008)). If in the baseline scenario at least 25% of the project area would burn at least once every 10 years and if rewetting and fire fighting in the project scenario would stop all carbon losses from microbial peat oxidation and all carbon losses from fire, the peat fire emission reduction would be 25% of the emission reduction from microbial peat oxidation. The 20% default premium is thus a conservative value.

The fire reference period is fixed to a period prior to project start to prevent deliberate fires to meet the eligibility criteria. A minimum period of 10 years must be assessed in order to ensure a representative time period that will reflect frequency of fires in the baseline.

In this procedure, the CO_2 emission reductions from microbial peat oxidation due to rewetting in the project scenario are estimated first (Sections 8.1.3 and 8.2.3 and Equation 48). The default value for reduced emissions from peat fire has a maximum of 20% of the reduced CO_2 emissions from microbial peat oxidation due to rewetting, if the cumulative area[23] burnt in the fire reference period was equal to or exceeded 25% of the project area. This amount of emission reductions

[22] Conservatively assuming that all carbon losses from peat fires occur as CO_2.
[23] The maximum number of times a recurring fire can be counted is 3.

(Equation 48) is denoted '*Fire Reduction Premium*'. The project will only be eligible to claim the premium if the following applies:

1) Over the period of 10 to 15 years, ending 2 years before the project start date, the cumulative area of peat burnt exceeded 10% of the project area (where repeated burning of the same area adds to the percentage). Evidence must be provided using statistics and/or maps in official reports and/or remote sensing data; and,
2) In the baseline scenario the area is now, and in future will be, under risk of anthropogenic peat fires, as demonstrated by current and historic fire statistics and/or fire maps for the project area, in combination with information on current and future land use; and,
3) The fire management plan proposed by the project proponent at validation reflects the best practices available with respect to fire prevention and control as determined by the relevant authorities[24] and takes into account specific project circumstances; and,
4) At each verification, documentation is provided demonstrating that fire management activities have been implemented according to the proposed plan.

If peat fires in the baseline scenario are more frequent than once per 10 years or more extensive than 25% of the project area, the awarded premium is more conservative. If peat fires are less frequent or extensive, the premium is smaller accordingly. If peat fires in the baseline are less extensive than 10% of the project area, the premium is not awarded.

If $(A_{peatburn} / A_P) \geq 0.25$ the emission reduction from peat combustion due to rewetting and fire management is estimated as:

$$Fire\ Reduction\ Premium = 0.20 \times (GHG_{GESTbsl\text{-}CO2} - GHG_{GESTwps\text{-}CO2}) \quad \textbf{(48)}$$

If $(A_{peatburn} / A_P) < 0.1$ then

$$Fire\ Reduction\ Premium = 0 \quad \textbf{(49)}$$

If $(A_{peatburn} / A_P) < 0.25$ and $A_{peatburn} / A_P \geq 0.1$ then

$$Fire\ Reduction\ Premium = (A_{peatburn} / A_P) \times 0.8 \times (GHG_{GESTbsl\text{-}CO2} - GHG_{GESTwps\text{-}CO2}) \quad \textbf{(50)}$$

$$GHG_{GESTbsl\text{-}CO2} = \sum_{t=1}^{t^*} \sum_{i=1}^{M_{BSL}} GHG_{GESTbsl\text{-}CO2,i,t} \quad \textbf{(51)}$$

$$GHG_{GESTwps\text{-}CO2} = \sum_{t=1}^{t^*} \sum_{i=1}^{M_{BSL}} GHG_{GESTwps\text{-}CO2,i,t} \quad \textbf{(52)}$$

Where:

Fire Reduction Premium Greenhouse gas emission reduction from peat combustion due to

[24] Verifiable evidence must be provided in the project documentation.

	rewetting and fire management up to year t^*; t CO_2e
$GHG_{GESTbsl\text{-}CO2}$	Emission of CO_2 from GESTs in the baseline scenario up to year t^*; t CO_2e
$GHG_{GESTwps\text{-}CO2}$	Emission of CO_2 from GESTs in the project scenario up to year t^*; t CO_2e
$GHG_{GESTbsl\text{-}CO2,i,t}$	Emission of CO_2 from baseline GEST in stratum i in year t; t CO_2e yr^{-1}
$GHG_{GESTwps\text{-}CO2,i,t}$	Emission of CO_2 from project GEST in stratum i in year t; t CO_2e yr^{-1}
$A_{peatburn}$	Cumulative area burnt; ha
A_P	Total project area; ha
i	1, 2, 3, … M_{BSL} strata in the baseline scenario
t	1, 2, 3, … t^* years elapsed since the project start

Fire Reduction Premium may be calculated on a total project basis, which implies that the documentation referred to in requirements 3 and 4 above are provided at the project level. Alternatively, the assessment may be executed at the sub-project level, for example if the project is made up of a number of different peat bogs or fens that have different baseline fire histories, or in case of instances in a Grouped Project.

Ex-ante estimate of *Fire Reduction Premium*: The estimate of $GHG_{GESTwps\text{-}CO2,i,t}$ in Equation 52 must be taken from *ex-ante* calculations (Section 8.2.3.2).

Ex-post estimate of *Fire Reduction Premium*: The estimate of $GHG_{GESTwps\text{-}CO2,i,t}$ in Equation 52 must be taken from monitoring results.

If a) peatland rewetting and b) a best-practices fire management have been implemented, peat fires occurring in the project scenario can be assumed to be catastrophic reversals[25] (i.e. events that would have occurred in the baseline scenario but that would have been unaccounted for). Therefore, provided the above-mentioned two conditions are met, such fire events will not affect the claim to fire emission reduction by the project.

Although rewetting and fire management are aimed at stopping fire in the project scenario, rewetting and fire management may fail, causing peatland fires to occur. Peatland fires inside the project boundary must, therefore, be monitored and – if not catastrophic as defined above – accounted for by cancelling the premium for the entire project or the individual sub-project, as in:

$$\textit{Fire Reduction Premium} = 0 \qquad \textbf{(53)}$$

In case of non-catastrophic fires, adjustments must be made for subsequent changes in carbon store and GHG fluxes (e.g., peat stocks at t=100).

[25] See *VCS Program Definitions* for definition of catastrophic reversal.

8.4 Leakage

Under the applicability conditions of this methodology, market leakage and activity shifting leakage do not occur. Project proponents must demonstrate, based on verifiable information (such as laws and bylaws, management plans, market reports) that in case the pre-project land use is one or a combination of the following:

- Forestry, this forestry is non-commercial in nature;
- Peat extraction, this activity has been abandoned at least 2 years[26] prior to the project start date;
- Agriculture, food, fodder or fiber production has been abandoned at least 2 years prior to the project start date, or will continue in the project scenario, or drainage of additional peatland for new agricultural sites will not occur or is prohibited by law;
- Fuel wood extraction, the activity is non-commercial in nature.

Under the applicability conditions of this methodology, ecological leakage also does not occur, by ensuring that hydrological connectivity with adjacent areas is insignificant (i.e. causing no alteration of mean annual water table depths in such areas). This can be achieved either by an appropriate design (e.g., by establishing an impermeable dam) or by a buffer zone within the project boundary for which conservatively no GHG benefits are accounted. This buffer zone, if employed, must be mapped and is not eligible for carbon crediting. The width of the buffer zone must be determined on the basis of quantitative hydrological modeling, or expert judgment. Procedures for monitoring are provided in Sections 9.3.4 and 9.3.6.

Therefore:

$$GHG_{LK} = 0 \qquad \textbf{(54)}$$

8.5 Summary of GHG Emission Reduction and/or Removals

8.5.1 Calculation of net GHG emissions reductions

The total net GHG emission reductions from the RDP project activity are calculated as follows:

$$NER_{RDP} = GHG_{BSL} - GHG_{WPS} + Fire\ Reduction\ Premium - GHG_{LK} \qquad \textbf{(55)}$$

[26] Agents abandoning peat extraction for the purpose of a rewetting project are unlikely to exist, because the investments in making a new area suitable for peat extraction by far exceed the revenues of a carbon project on the same area.

Where the direct estimate approach in estimating emission reductions due to rewetting (Section 8.2.3.2) is adopted, the total net GHG emission reductions are calculated as follows:

$$NER_{RDP} = 44/12 \times (\Delta C_{BSL} - \Delta C_{WPS}) + \Delta GHG_{rewetting} + \mathit{Fire\ Reduction\ Premium} - GHG_{LK} \quad \textbf{(56)}$$

Where:

NER_{RDP}	Total net CO_2 equivalent emission reductions from the RDP project activity up to year t^*; t CO_2e
GHG_{BSL}	Net CO_2 equivalent emissions in the baseline scenario up to year t^*; t CO_2e
GHG_{WPS}	Net CO_2 equivalent emissions in the project scenario up to year t^*; t CO_2e
ΔC_{BSL}	Net carbon stock change in non-peat carbon pools in the baseline scenario up to year t^*; t C
ΔC_{WPS}	Net carbon stock change in non-peat carbon pools in the project scenario up to year t^*; t C
$\Delta GHG_{rewetting}$	Greenhouse gas emission reduction due to rewetting up to year t^*; t CO_2e
Fire Reduction Premium	Greenhouse gas emission reduction from peat combustion due to rewetting and fire management up to year t^*; t CO_2e
GHG_{LK}	Net CO_2 equivalent emissions in the project scenario due to leakage up to year t^*; t CO_2e

NER_{RDP} must be corrected for uncertainty, by estimating the total uncertainty for the RDP project activity (NER_{RDP_ERROR}) as provided in Section 8.5.2.

8.5.2 Estimation of uncertainty

This procedure allows for estimating uncertainty in the estimation of emissions and carbon stock changes (i.e., a procedure for calculating a precision level and any deduction in credits for lack of precision following project implementation and monitoring, by assessing uncertainty in baseline and project estimations).

This procedure focuses on the following sources of uncertainty:

- Uncertainty associated with estimation of stocks in carbon pools and changes in carbon stocks
- Uncertainty in assessment of project emissions

Where an uncertainty value is not known or cannot be simply calculated, then the project proponent must justify that it is using a conservative number and an uncertainty of 0% may be used for this component.

Guidance on uncertainty – a precision target of a 90% or 95% confidence interval equal to or less than 20% or 30%, respectively, of the recorded value must be targeted. This is especially important in terms of project planning for measurement of carbon stocks where sufficient measurement plots should be included to achieve this precision level across the measured stocks.

Required conditions:

- Levels of uncertainty must be known for all aspects of baseline and project implementation and monitoring. Uncertainty will generally be known as the 90% or 95% confidence interval expressed as a percentage of the mean.
- Where uncertainty is not known it must be demonstrated that the value used is conservative.

Estimated carbon emissions and removals arising from AFOLU activities have uncertainties associated with the measures/estimates of: area or other activity data, carbon stocks, biomass growth rates, expansion factors, and other coefficients. It is assumed that the uncertainties associated with the estimates of the various input data are available, either as default values given in IPCC Guidelines (2006), IPCC GPG-LULUCF (2003), expert judgment, or estimates based of sound statistical sampling.

Alternatively, conservative estimates can also be used instead of uncertainties, provided that they are based on verifiable literature sources or expert judgment. In this case the uncertainty is assumed to be zero. However, this tool provides a procedure to combine uncertainty information and conservative estimates resulting in an overall *ex-post* project uncertainty.

Planning to Diminish Uncertainty

It is important that the process of project planning consider uncertainty. Procedures including stratification and the allocation of sufficient measurement plots can help ensure that low uncertainty in carbon stocks results and ultimately full crediting can result.

It is good practice to apply this procedure at an early stage to identify the data sources with the highest uncertainty to allow the opportunity to conduct further work to diminish uncertainty.

Part 1 – Uncertainty in Baseline Estimates

$$Uncertain_{BSL,i} = \frac{\sqrt{\left(U_{BSL,SS1,i} * E_{BSL,SS1,i}\right)^2 + \left(U_{BSL,SS2,i} * E_{BSL,SS2,i}\right)^2 \cdots + \cdots \left(U_{BSL,SSn,i} * E_{BSL,SSn,i}\right)^2}}{E_{BSL,SS1,i} + E_{BSL,SS2,i} \cdots + \cdots E_{BSL,SSn,i}} \quad \textbf{(57)}$$

Where:

$Uncertain_{BSL,i}$	Percentage uncertainty in the combined carbon stocks and greenhouse gas sources in the baseline case in stratum *i*; %
$U_{BSL,SS,i}$	Percentage uncertainty (expressed as 90% confidence interval as a percentage of the mean where appropriate) for carbon stocks and greenhouse gas sources in the baseline case in stratum *i* (1,2, … n represent different carbon pools and/or GHG sources); %
$E_{BSL,SS,i}$	Carbon stock or GHG sources (e.g., trees, down dead wood, etc.) in stratum *i* (1,2, … n represent different carbon pools and/or GHG sources) in the baseline case; t CO_2e
i	1, 2, 3, … M_{BSL} strata in the baseline scenario

To assess uncertainty across combined strata:

$$Uncertain_{BSL} = \frac{\sqrt{(U_{BSL,1} * A_1)^2 + (U_{BSL,2} * A_2)^2 \ldots + \ldots (U_{BSL,M_{BSL}} * A_{M_{BSL}})^2}}{A_1 + A_2 \ldots + \ldots A_{M_{BSL}}} \tag{58}$$

Where:

$Uncertain_{BSL}$	Total uncertainty in baseline scenario; %
$U_{BSL,i}$	Uncertainty in baseline scenario in stratum *i*; %
A_i	Area of stratum *i*; ha
i	1, 2, 3, … M_{BSL} strata in the baseline scenario

Part 2 – Uncertainty Ex-Post in the Project Scenario

$$Uncertain_{WPS,i} = \frac{\sqrt{(U_{WPS,SS1,i} * E_{WPS,SS1,i})^2 + (U_{WPS,SS2,i} * E_{WPS,SS2,i})^2 \ldots + \ldots (U_{WPS,SSn,i} * E_{WPS,SSn,i})^2}}{E_{WPS,SS1,i} + E_{WPS,SS2,i} \ldots + \ldots E_{WPS,SSn,i}} \tag{59}$$

Where:

$Uncertain_{WPS,i}$	Percentage uncertainty in the combined carbon stocks and greenhouse gas sources in the project case in stratum *i*; %
$U_{WPS,SS,i}$	Percentage uncertainty (expressed as 90% confidence interval as a percentage of the mean where appropriate) for carbon stocks and greenhouse gas sources in the project case in stratum *i* (1,2, … n represent different carbon pools and/or GHG sources); %
$E_{WPS,SS,i}$	Carbon stock or GHG sources (e.g., trees, down dead wood, etc.) in stratum *i* (1,2, … n represent different carbon pools and/or GHG sources) in the project case; t CO_2e

i	1, 2, 3, … M_{WPS} strata in the project scenario

To assess uncertainty across combined strata:

$$Uncertain_{WPS} = \frac{\sqrt{(U_{WPS,1} * A_1)^2 + (U_{WPS,2} * A_2)^2 \ldots + \ldots (U_{WPS,M_{BSL}} * A_{M_{BSL}})^2}}{A_1 + A_2 \ldots + \ldots A_{M_{BSL}}} \quad (60)$$

Where:

$Uncertain_{WPS}$	Total uncertainty in project scenario; %
$U_{WPS,i}$	Uncertainty in project scenario in stratum i; %
A_i	Area of stratum i; ha
i	1, 2, 3, … M_{WPS} strata in the project scenario

Part 3 – Total Error in RDP Project Activity

$$NER_{RDP\_ERROR} = \frac{\sqrt{(Uncertain_{BSL} \times GHG_{BSL})^2 + (Uncertain_{WPS} \times GHG_{WPS})^2}}{GHG_{BSL} + GHG_{WPS}} \quad (61)$$

Where:

NER_{RDP_ERROR}	Total uncertainty for RDP project activity; %
$Uncertain_{BSL}$	Total uncertainty in baseline scenario; %
$Uncertain_{WPS}$	Total uncertainty in the project scenario; %
GHG_{BSL}	Net CO_2 equivalent emissions in the baseline scenario up to year t^*; t CO_2e
GHG_{WPS}	Net CO_2 equivalent emissions in the project scenario up to year t^*; t CO_2e

The allowable uncertainty under this methodology is 20% or 30% of $NER_{RDP,t}$ at a 90% or 95% confidence level, respectively. Where this precision level is met no deduction should result for uncertainty. Where exceeded, the deduction must be equal to the amount that the uncertainty exceeds the allowable level. The adjusted value for $NER_{RDP,t}$ to account for uncertainty must be calculated as:

$$adjusted\_NER_{RDP,t} = NER_{RDP,t} \times (100\% - NER_{RDP\_ERROR} + allowable\_uncert) \quad (62)$$

Where:

$adjusted\_NER_{RDP,t}$	Cumulative total net GHG emission reductions at time t adjusted to account for uncertainty; t CO_2e
$NER_{RDP,t}$	Total net GHG emission reductions from the RDP project activity up to year t; t CO_2e

NER_{RDP_ERROR}	Total uncertainty for RDP project activity; %
allowable_unsert	Allowable uncertainty; 20% or 30% at a 90% or 95% confidence level, respectively; %

8.5.3 Calculation of Verified Carbon Units

The concept of withholding a number of buffer credits in the AFOLU pooled buffer account is based on quantifying the net change in carbon stocks. The proxy for the net change in carbon stocks applied in this methodology is NER (Section 8.5.1). As this proxy includes all net GHG emissions reductions, it provides a conservative (too large) estimate of the buffer withholding.

The number of Verified Carbon Units is calculated as:

$$VCU_{t2} = \left(adjusted\_NER_{RDP,t2} - adjusted\_NER_{RDP,t1}\right) - Bufferw_{t2} \quad \textbf{(63)}$$

Where:

VCU_{t2}	Number of Verified Carbon Units in year *t2*
$NER_{RDP,\ t1}$	Total net GHG emission reductions from the RDP project activity up to year *t1*; t CO_2e
$NER_{RDP,\ t2}$	Total net GHG emission reductions from the RDP project activity up to year *t2*; t CO_2e
NER_{RDP_ERROR}	Total uncertainty for RDP project activity; %
$Bufferw_{t2}$	Number of Verified Carbon Units to be withheld in the VCS Buffer in year *t2*

$$Bufferw_{t2} = \left(NER_{RDP,t2} - NER_{RDP,t1}\right) \times Buffer\%_{t2} \quad \textbf{(64)}$$

Where:

$Bufferw_{t2}$	Number of Verified Carbon Units to be withheld in the VCS Buffer in year *t2*
$NER_{RDP,\ t1}$	Total net GHG emission reductions from the RDP project activity up to year *t1*; t CO_2e
$NER_{RDP,\ t2}$	Total net GHG emission reductions from the RDP project activity up to year *t2*; t CO_2e
$Buffer\%_{t2}$	Percentage of Verified Carbon Units to be withheld in the VCS Buffer in year *t2*; %

The percentage to be withheld in the VCS buffer is to be determined using the latest version of the VCS *AFOLU Non-Permanence Risk Tool*.

The maximum quantity of GHG emission reductions that may be claimed by the project (VCU_{max}) is limited to the difference between project and baseline scenario after a 100-year time frame.

Procedures for estimating the difference between peat carbon stock in the project scenario and baseline scenario in stratum *i* at *t*=100 ($C_{WPS\text{-}BSL,i,t100}$) are provided in Section 5.2.

$$VCU_{max} = \frac{44}{12} \times C_{WPS-BSL,t100} \quad (65)$$

Where:

VCU_{max}	The maximum quantity of GHG emission reductions that may be claimed by the project ; t CO_2e
$C_{WPS\text{-}BSL,t100}$	Difference between peat carbon stock in the project scenario and baseline scenario at *t*=100; t C ha^{-1}

9 MONITORING

9.1 Data and Parameters Available at Validation

Data Unit / Parameter:	$Depth_{peat\text{-}BSL,i}$
Data unit:	m
Description:	Peat depth above the drainage limit in the baseline scenario in stratum *i* at project start
Equations	1, 4, 5
Source of data:	Own measurements and/or literature involving the project area
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	Peat depths at project start can be derived from • Own measurements (using peat corers, ground penetrating radar or other techniques laid out in scientific literature or handbooks) • Literature involving the project or similar areas.
Purpose of Data	Calculation of baseline emissions Calculation of the maximum quantity of GHG emission reductions that may be claimed by the project
Comments:	$Depth_{peat\text{-}BSL,i,t0} = Depth_{peat\text{-}WPS,i,t0}$ This parameter must be re-assessed together with the re-assessment of the baseline scenario.

Data Unit / Parameter:	$Depth_{peat\text{-}WPS,i}$

Data unit:	m
Description:	Peat depth above the drainage limit in the project scenario in stratum *i* at project start
Equations	6
Source of data:	As for $Depth_{peat\text{-}BSL,i}$
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	As for $Depth_{peat\text{-}BSL,i}$
Purpose of Data	Calculation of the maximum quantity of GHG emission reductions that may be claimed by the project
Comments:	Only for *ex-ante* assessment $Depth_{peat\text{-}BSL,i,t0} = Depth_{peat\text{-}WPS,i,t0}$

Data Unit / Parameter:	$Rate_{peatloss\text{-}BSL,i}$
Data unit:	m yr^{-1}
Description:	Rate of peat loss due to subsidence and fire in the baseline scenario in stratum *i*
Equations	1, 5, 9
Source of data:	Own measurements, expert judgment, datasets and/or literature of historic subsidence
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	The rate of peat loss due to subsidence must be based on verifiable information and can be derived from 1. Expert judgment, datasets and/or literature of historic subsidence involving the project or similar areas, based on surface height measurements relative to a fixed reference point in m asl (e.g., using poles fixed in the underlying mineral soil or rock, or using LiDAR, or similar). Information used must be verifiable. Or 2. CO_2 emissions derived from the prevalent GESTs (Section 8.1.3), in combination with data on volumetric carbon content of the peat. Divide the annual CO_2 emission (t CO_2 ha^{-1}) by 44/12, then divide by volumetric carbon

	content (g C cm^{-3}) to obtain height loss in m. The average depth of burn scars can be derived from expert judgment, datasets and/or literature of historic burn depths involving the project or similar areas, based on surface height measurements (e.g., using field measurements or LiDAR). When using LiDAR data, projects must use a scientifically robust approach, referring to pertinent scientific literature, ensuring a horizontal accuracy in the meter and a vertical accuracy in the centimeter range. In case of tree cover, scientifically accepted methods must be used to distinguish ground points from non-ground points reflected by the vegetation. Projects may, for example, use the procedures described in Ballhorn *et al*. (2009). Projects may deviate from these procedures provided that the accuracy requirements above are met. The areal extent of burn scars can be obtained from statistics and/or maps in official reports and/or field measurements or remote sensing data (similar materials as required under eligibility criteria 1 and 2 in Section 8.3(*Fire Reduction Premium*), A mean annualized burn depth must be calculated and applied to the entire project area. As only part of the project area is likely to burn in the baseline, this constitutes a conservative approach. The project proponent must demonstrate, using expert judgment, datasets and/or scientific literature that the accuracy of the derived rate of peat loss is sufficient to fulfill the criteria set out in Section 5.2(Stratification). Similarity of areas must be illustrated (by own measurements, literature resources, datasets or a combination of these) addressing peat type, climatic conditions, land use (forestry, agriculture, peat extraction, or abandonment after these activities), and average annual water table depth (±20%). In case of dissimilarity, the project proponent must demonstrate that such difference gives a conservative result for the net GHG benefits of the project. Forecasting peat subsidence rates must be based on the conservative extrapolation of a historic trend, or conservative modeling of proxies such as water table depth and land use type.
Purpose of Data	Calculation of baseline emissions

	Calculation of the maximum quantity of GHG emission reductions that may be claimed by the project
Comments:	The use of a relatively low value for a constant rate of peat loss may not be confused with a relatively high value when determining the need for stratification of peat depth. This parameter must be re-assessed together with the re-assessment of the baseline scenario.

Data Unit / Parameter:	$Rate_{peatloss\text{-}WPS,i}$
Data unit:	m yr^{-1}
Description:	Rate of peat loss due to subsidence in the project scenario in stratum *i*
Equations	6, 10
Source of data:	Own measurements, expert judgment, datasets and/or literature of historic subsidence
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	The rate of peat loss due to subsidence must be based on verifiable information and can be derived from 1. Expert judgment, datasets and/or literature of subsidence involving areas representing conditions similar to the project, based on surface height measurements relative to a fixed reference point in m asl (e.g., using poles fixed in the underlying mineral soil or rock, or by using LiDAR following methods such as those described in Ballhorn *et al*. 2009) or similar. Or 2. CO_2 emissions derived from the prevalent GESTs based on *ex-ante* scenario definitions (Section 8.2.3), in combination with data on volumetric carbon content of the peat. Divide the annual CO_2 emission (t CO_2 ha^{-1}) by 44/12, then divide by volumetric carbon content (g C cm^{-3}) to obtain height loss in m. The project proponent must demonstrate, using expert judgment, datasets and/or scientific literature that the accuracy of the derived rate of peat loss is sufficient to fulfill the criteria set out in Section 5.2(Stratification).

	Similarity of areas must be illustrated (by own measurements, literature resources, datasets or a combination of these) addressing peat type, climatic conditions, land use (forestry, agriculture, peat extraction, or abandonment after these activities), and average annual water table depth (±20%). In case of dissimilarity, the project proponent must demonstrate that such difference gives a conservative result for the net GHG benefits of the project.
Purpose of Data	Calculation of the maximum quantity of GHG emission reductions that may be claimed by the project
Comments:	Only for *ex-ante* assessment

Data Unit / Parameter:	VC_{peat}
Data unit:	t C m^{-3}
Description:	Volumetric carbon content of peat
Equations	3, 4, 9, 10
Source of data:	The volumetric carbon content in peat can be taken from own measurements within the project area or from literature involving the project or similar areas.
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	Applied techniques shall follow international standards of application or local standards as laid out in pertinent scientific literature or handbooks.
Purpose of Data	Calculation of the maximum quantity of GHG emission reductions that may be claimed by the project
Comments:	N/A

Data Unit / Parameter:	$A_{BSL,i,t}$
Data unit:	ha
Description:	Area of baseline stratum *i* in year *t*
Equations	2, 7, 8, 11, 14, 26, 27, 43
Source of data:	Own assessment
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures	Delineation of strata must be done preferably using a geographical information system (GIS), which allows for integrating data from different sources (including GPS

applied:	coordinates and remote sensing data). Applied techniques shall follow international standards of application or local standards as laid out in pertinent scientific literature or handbooks.
Purpose of Data	Calculation of baseline emissions
Comments:	In Equations 2, 7, 8 and 11 the parameter is denoted as $A_{BSL,i,t100}$, which is the area of baseline stratum *i* at *t*=100.

Data Unit / Parameter:	R_j
Data unit:	t root d.m. t^{-1} shoot d.m.
Description:	Root:shoot ratio for tree species *j*
Equations	17, 33
Source of data:	The source of data must be chosen with priority from higher to lower preference as follows: (a) National and species-specific or group of species-specific (e.g., from national GHG inventory); (b) Species-specific or group of species-specific from neighboring countries with similar conditions. Sometimes b) might be preferable to a); (c) Species-specific or group of species-specific from global studies. See also IPCC GPG 2003, Annex 3.A1, Table 3A1.8
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	Taken from CDM A/R methodology
Purpose of Data	Calculation of baseline emissions Calculation of project emissions
Comments:	

Data Unit / Parameter:	CF_j
Data unit:	t C t $d.m.^{-1}$
Description:	Carbon fraction of dry matter for species *j*
Equations	19, 22, 23, 31, 34
Source of data:	IPCC default value

Value applied:	0.5
Justification of choice of data or description of measurement methods and procedures applied:	IPCC is a reputable source approved by the VCS
Purpose of Data	Calculation of baseline emissions Calculation of project emissions
Comments:	N/A

Data Unit / Parameter:	$I_{v,j,i,t}$
Data unit:	$m^{-3}ha^{-1}yr^{-1}$
Description:	Average annual increment in merchantable volume for species *j* in stratum *i* in year *t*
Equations	20
Source of data:	Based on monitored parameters (species, yield class, age) to be found in regional forest growth tables.
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	Common source of data in forestry
Purpose of Data	Calculation of baseline emissions
Comments:	N/A

Data Unit / Parameter:	D_j
Data unit:	t d.m. m^{-3}
Description:	Basic wood density for species *j*
Equations	20, 22, 31
Source of data:	Datasets or literature
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	Values for D_j can be taken from tables generally used in the local or regional timber and forest industry, or from peer-reviewed literature applicable to the region. If no species-specific values for D_j are available, the average value across all species can be used, increased by 20% to ensure conservative estimates in the baseline, or decreased by

	20% to ensure conservative estimates in the project scenario. The source of data must be chosen with priority from higher to lower preference as follows: (a) National and species-specific or group of species-specific (e.g., from national GHG inventory); (b) (Group of) Species-specific from neighbouring countries with similar conditions. Sometimes b) might be preferable to a); (c) Globally species-specific or group of species-specific (e.g., IPCC GPG-LULUCF 2003). This is taken from a CDM A/R methodology.
Purpose of Data	Calculation of baseline emissions Calculation of project emissions
Comments:	N/A

Data Unit / Parameter:	$BEF_{1,j}$
Data unit:	dimensionless
Description:	Biomass expansion factor for conversion of annual net increment (including bark) in merchantable volume to total above-ground biomass increment for species *j*
Equations	20
Source of data:	The source of data must be chosen with priority from higher to lower preference as follows: a. Existing local and species-specific or group of species-specific; b. National and species-specific or group of species-specific (e.g., from national GHG inventory) c. Species-specific or group of species-specific from neighbouring countries with similar conditions (might be preferable to b under certain conditions) d. Climatic zone and forest type (eg IPCC literature: Table 3A.1.10 of the GPG-LULUCF (IPCC 2003) and Table 4.5 of the AFOLU Guidelines (IPCC 2006)
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures	Taken from CDM A/R methodology

applied:	
Purpose of Data	Calculation of baseline emissions
Comments:	*BEFs* are age dependent, and they are usually large for young stands and quite small for old stands; *BEFs* in IPCC literature and national inventory data are usually applicable to closed canopy forest. If applied to individual trees growing in open field it is recommended that the selected *BEF* be increased by a further 30%.

Data Unit / Parameter:	K_{ph}
Data unit:	dimensionless
Description:	Alexeyev coefficient, converts volumes of above ground growing stock ($m^3 ha^{-1}$) to above, below ground and bark dry biomass (t d.m. ha^{-1})
Equations	-
Source of data:	Alexeyev *et al*. (1995). Carbon in vegetation in Russian forests: methods to estimate storage and geographical distribution. Water, Air Soil Pollution 82: 271-282
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	Peer-reviewed literature is a VCS-approved source
Purpose of Data	Calculation of baseline emissions
Comments:	May be used instead of R_j and BEF_j

Data Unit / Parameter:	$V_{j,i,t}$
Data unit:	m^3 ha^{-1}
Description:	Stem volume of tree species *j* in stratum *i* in year *t*
Equations	22
Source of data:	Datasets or literature
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures	Common source of data in forestry

applied:	
Purpose of Data	Calculation of baseline emissions
Comments:	Note that volume tables from which $V_{j,i,t}$ are obtained may or may not include allowance for losses due to harvesting or mortality. Such losses may be conservatively neglected when estimating baseline removals in pre-project trees. Otherwise $C_{BSL\text{-}tree\text{-}AB,j,i,t}$ must be estimated on the basis of credible and transparent information on the rate at which pre-project activities (and mortality, if applicable) are reducing carbon stocks in existing live trees (e.g., due to harvesting for local timber consumption, or for fuelwood).

Data Unit / Parameter:	BEF_{2j}
Data unit:	dimensionless
Description:	Biomass expansion factor for conversion of stem biomass to above-ground tree biomass for species *j*
Equations	22, 31
Source of data:	The source of data must be chosen with priority from higher to lower preference as follows: a. Existing local and species-specific or group of species-specific; b. National and species-specific or group of species-specific (e.g., from national GHG inventory) c. Species-specific or group of species-specific from neighbouring countries with similar conditions (might be preferable to b under certain conditions) d. Climatic zone and forest type (e.g., IPCC literature: Table 3A.1.10 of the GPG-LULUCF (IPCC 2003) and Table 4.5 of the AFOLU Guidelines (IPCC 2006)
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	Taken from CDM A/R methodology
Purpose of Data	Calculation of baseline emissions Calculation of project emissions
Comments:	

Data Unit / Parameter:	$nTR_{j,i,t}$
Data unit:	trees ha^{-1}
Description:	Tree stand density of species *j* in stratum *i* in year *t*
Equations	23
Source of data:	Field measurement in sample plots or from forest inventory
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	Applied techniques shall follow international standards of application or local standards as laid out in pertinent scientific literature or handbooks.
Purpose of Data	Calculation of baseline emissions
Comments:	N/A

Data Unit / Parameter:	$f_j(X, Y, …)$
Data unit:	t d.m. tree^{-1}
Description:	Allometric equation for species *j* linking measured tree dimension variables (e.g., diameter at breast height (*DBH*) and possibly height (*H*)) to above-ground biomass of living trees.
Equations	23
Source of data:	Own measurements or literature, or both
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	The allometric equations are preferably locally derived and species specific. When allometric equations developed from a biome-wide database, such as those in Annex 4A.2, Tables 4.A.1 and 4.A.2 of IPCC GPG LULUCF, are used, it is necessary to verify by destructively harvesting, within the project area but outside the sample plots, a few trees of different sizes and estimate their biomass and then compare against a selected equation. If the biomass estimated from the harvested trees is within about □1 by the equation, then it can be assumed that the selected equation is suitable for the project. If this is not the case, it is recommended to develop local allometric equations for the project use. For this, a sample of trees, representing different size classes, is destructively harvested, and its total biomass is determined. The number of trees to be destructively harvested and measured depends on the

	range of size classes and number of species—the greater the heterogeneity the more trees are required.
Purpose of Data	Calculation of baseline emissions Calculation of project emissions
Comments:	Used for trees known at validation

Data Unit / Parameter:	$GHG_{GESTbsl\text{-}CO2,i,t}$
Data unit:	t CO_2e $ha^{-1}yr^{-1}$
Description:	Emission of CO_2 from baseline GEST in stratum *i* in year *t*
Equations	26, 43
Source of data:	Data can be obtained from peer-reviewed literature or from own measurements.
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	See Section 9.3.6 for procedures to describe and quantify this proxy.
Comments:	This parameter must be re-assessed together with the re-assessment of the baseline scenario.

Data Unit / Parameter:	$GHG_{WLbsl\text{-}CO2,i,t}$
Data unit:	t CO_2e $ha^{-1}yr^{-1}$
Description:	Emission of CO_2 related to water table depth in the baseline scenario in stratum *i* in year *t*
Equations	27
Source of data:	Data can be obtained from peer-reviewed literature or from own measurements.
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	See Section 9.3.6 for procedures to quantify this proxy. The project may establish project-specific values for $GHG_{WLbsl\text{-}CO2}$ or apply values from appropriate literature sources pertaining to land use classes, or water table depths or water table depth classes and similar project circumstances. For such literature values the accuracy must be defined or conservativeness must be justified. Project circumstances are defined by pre-project land use (e.g., forestry, peat mining, agriculture, abandonment after such

	activities) and its intensity, climatic zone, water table depths, and peat type. If the mean annual water table depth in the project area exceeds the depth range for which the emission-vegetation or emission-water table depth relationship determined for the project is valid, a conservative extrapolation must be used.
Purpose of Data	Calculation of baseline emissions
Comments:	This parameter must be re-assessed together with the re-assessment of the baseline scenario.

Data Unit / Parameter:	$GHG_{GESTbsl\text{-}CH4,i,t}$
Data unit:	t CO_2e $ha^{-1}yr^{-1}$
Description:	Emission of CH_4 from baseline GEST in stratum *i* in year *t*
Equations	26, 43
Source of data:	Data can be obtained from peer-reviewed literature or from own measurements.
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	See Section 9.3.6 for procedures to describe and quantify this proxy.
Purpose of Data	Calculation of baseline emissions
Comments:	This parameter must be re-assessed together with the re-assessment of the baseline scenario.

Data Unit / Parameter:	$GHG_{WLbsl\text{-}CH4,i,t}$
Data unit:	t CO_2e $ha^{-1}yr^{-1}$
Description:	Emission of CH_4 related to water table depth in the baseline scenario in stratum *i* in year *t*
Equations	27
Source of data:	Data can be obtained from peer-reviewed literature or from own measurements.
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	See Section 9.3.6 for procedures to quantify this proxy. The project may establish project-specific values for $GHG_{WLbsl\text{-}CH4}$ or apply values from appropriate literature sources pertaining to land use classes, or water table

	depths or water table depth classes and similar project circumstances. For such literature values the accuracy must be defined or conservativeness must be justified. Project circumstances are defined by pre-project land use (e.g., forestry, peat mining, agriculture, abandonment after such activities) and its intensity, climatic zone, water table depths, and peat type. If the mean annual water table depth in the project area exceeds the depth range for which the emission-vegetation or emission-water table depth relationship determined for the project is valid, a conservative extrapolation must be used. $GHG_{WLbsl\text{-}CH4}$ may be conservatively neglected.
Purpose of Data	Calculation of baseline emissions
Comments:	This parameter must be re-assessed together with the re-assessment of the baseline scenario.

Data Unit / Parameter:	$V_{l,j,i,sp,t}$
Data unit:	m^3 $tree^{-1}$
Description:	Stem volume of tree *l* of species *j* in plot *sp* in stratum *i* in year *t*
Equations	35
Source of data:	$V_{l,j,i,sp,t}$ is based on available equations or yield tables (if locally derived equations or yield tables are not available use relevant regional, national or default data as appropriate).
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	Common source of data in forestry
Purpose of Data	Calculation of baseline emissions
Comments:	N/A

Data Unit / Parameter:	$A_{peatburn}$
Data unit:	ha

Description:	Cumulative area burnt
Equations	50
Source of data:	Statistics and/or maps in official reports and/or remotes sensing data
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	The cumulative area burnt must be provided using statistics and/or maps in official reports and/or remotes sensing data. Repeated burning of the same area adds to the cumulative area. Delineation of the project area must be done preferably using a Geographical Information System (GIS), which allows for integrating data from different sources (including GPS coordinates and Remote Sensing data). Applied techniques shall follow international standards of application or local standards as laid out in pertinent scientific literature or handbooks.
Purpose of Data	Calculation of baseline emissions
Comments:	N/A

Data Unit / Parameter:	A_P
Data unit:	ha
Description:	Total project area
Equations	49, 50
Source of data:	Own assessment
Value applied:	n/a
Justification of choice of data or description of measurement methods and procedures applied:	Delineation of the project area must be done preferably using a Geographical Information System (GIS), which allows for integrating data from different sources (including GPS coordinates and Remote Sensing data). Applied techniques shall follow international standards of application or local standards as laid out in pertinent scientific literature or handbooks.
Purpose of Data	Calculation of baseline emissions
Comments:	N/A

9.2 Data and Parameters Monitored

Data Unit / Parameter:	$A_{WPS,i,t}$
Data unit:	ha
Description:	Area of project stratum *i* in year *t*
Equations:	2, 7, 8, 11, 30, 40, 43
Source of data:	Own assessment
Value applied:	n/a
Description of measurement methods and procedures to be applied:	Delineation of strata must be done preferably using a Geographical Information System (GIS), which allows for integrating data from different sources (including GPS coordinates and Remote Sensing data). Applied techniques shall follow international standards of application or local standards as laid out in pertinent scientific literature or handbooks.
Frequency of monitoring/recording:	Determined at each monitoring period
QA/QC procedures to be applied:	See Section 9.3.2
Purpose of Data:	Calculation of project emissions
Comments:	In Equations 2, 7, 8 and 11 the parameter is denoted as $A_{WPS,i,t100}$, which is the area of project stratum *i* at *t*=100.

Data Unit / Parameter:	$A_{sp,i}$
Data unit:	ha
Description:	Total area of all sample plots in stratum *i*
Equations:	37
Source of data:	Field measurements
Value applied:	n/a
Description of measurement methods and procedures to be applied:	Sample plots may be delineated on a map using a Geographical Information System (GIS). Alternatively, coordinates of sample plots map be stored in a GIS. The database must contain information on plot size and orientation. Applied techniques shall follow international standards of application or local standards as laid out in pertinent scientific literature or handbooks.

Frequency of monitoring/recording:	Determined at first monitoring period
QA/QC procedures to be applied:	See Section 9.3.2
Purpose of Data:	Calculation of project emissions
Comments:	N/A

Data Unit / Parameter:	$f_j(X, Y, \ldots)$
Data unit:	t d.m. tree^{-1}
Description:	Allometric equation for species *j* linking measured tree dimension variables (e.g., diameter at breast height (*DBH*) and possibly height (*H*)) to above-ground biomass of living trees.
Equations:	38
Source of data:	Own measurements or literature, or both
Value applied:	n/a
Description of measurement methods and procedures to be applied:	The allometric equations are preferably locally derived and species specific. When allometric equations developed from a biome-wide database, such as those in Annex 4A.2, Tables 4.A.1 and 4.A.2 of IPCC GPG LULUCF, are used, it is necessary to verify by destructively harvesting, within the project area but outside the sample plots, a few trees of different sizes and estimate their biomass and then compare against a selected equation. If the biomass estimated from the harvested trees is within about 10% of that predicted by the equation, then it can be assumed that the selected equation is suitable for the project. If this is not the case, it is recommended to develop local allometric equations for the project use. For this, a sample of trees, representing different size classes, is destructively harvested, and its total biomass is determined. The number of trees to be destructively harvested and measured depends on the range of size classes and number of species—the greater the heterogeneity the more trees are required.
Frequency of monitoring/recording:	Determined at first monitoring period
QA/QC procedures to be applied:	See Section 9.3.2

Purpose of Data:	Calculation of project emissions
Comments:	Used for trees monitored

Data Unit / Parameter:	*DBH*
Data unit:	cm
Description:	Diameter at breast height of tree
Equations:	38
Source of data:	Field measurement in sample plots
Value applied:	n/a
Description of measurement methods and procedures to be applied:	Measure all the trees above 5 cm DBH at typically 1.3 m above-ground level in the permanent sample plots. Applied techniques shall follow international standards of application or local standards as laid out in pertinent scientific literature or handbooks.
Frequency of monitoring/recording:	Determined at each monitoring period
QA/QC procedures to be applied:	See Section 9.3.2
Purpose of Data:	Calculation of project emissions
Comments:	N/A

Data Unit / Parameter:	*H*
Data unit:	m
Description:	Height of tree
Equations:	38
Source of data:	Field measurement in sample plots
Value applied:	n/a
Description of measurement methods and procedures to be applied:	Applied techniques shall follow international standards of application or local standards as laid out in pertinent scientific literature or handbooks.
Frequency of	Determined at each monitoring period

monitoring/recording:

Frequency of monitoring/recording:	Determined at each monitoring period
QA/QC procedures to be applied:	See Section 9.3.2
Purpose of Data:	Calculation of project emissions
Comments:	$T = t2 - t1$

9.3 Description of the Monitoring Plan

9.3.1 General

The main objective of project monitoring is to reliably quantify carbon stocks and GHG emissions in the project scenario during the project crediting period, prior to each verification, with the following main tasks:

- Monitoring of project carbon stock changes and GHG emissions
- Estimation of ex-post total net carbon stock changes and greenhouse gas emissions, and GHG emissions reductions

The monitoring plan must contain at least the following sections:

- A description of each monitoring task to be undertaken, and the technical requirements
- Parameters to be measured
- Data to be collected and data collection techniques
- Frequency of monitoring
- Quality Assurance and Quality Control (QA/QC) procedures
- Data archiving procedures
- Roles, responsibilities and capacity of monitoring team and management

9.3.2 Uncertainty and quality management

Quality management procedures are required for the management of data and information, including the assessment of uncertainty, relevant to the project and baseline scenarios. As far as practical, uncertainties related to the quantification of GHG emission reductions and removals by sinks should be reduced.

To help reduce uncertainties in the accounting of emissions and removals, this methodology uses whenever possible the proven methods from the GPG-LULUCF, GPG-2000, the IPCC's Revised 2006 Guidelines and peer-reviewed literature. Despite this, potential uncertainties still arise from the choice of parameters to be used. Uncertainties arising from input parameters would result in uncertainties in the estimation of both baseline net GHG emissions and project net GHG emissions - especially when global default values are used. The project proponent must identify key parameters that would significantly influence the accuracy of estimates. Local values that are specific to the project circumstances must then be obtained for these key parameters, whenever possible. These values should be based on:

- Data from well-referenced peer-reviewed literature or other well-established published sources[27]; or,
- National inventory data or default data from IPCC literature that has, whenever possible and necessary, been checked for consistency against available local data specific to the project circumstances; or
- In the absence of the above sources of information, expert opinion (see Section 9.3.3) may be used to assist with data selection. Experts will often provide a range of data, as well as a most probable value for the data. The rationale for selecting a particular data value must be briefly noted in the project documentation.

In choosing key parameters, or making important assumptions based on information that is not specific to the project circumstances, such as in use of default data, project proponents must select values that will lead to an accurate estimation of net GHG emission reductions, taking into account uncertainties.

If uncertainty is significant, project proponents must choose data such that it indisputably tends to under-estimate, rather than over-estimate, net GHG project benefits. For example, conservativeness in GHG emission reductions based on GESTs could be established by applying too low flux values to GESTs in the baseline. The conservativeness of the value (e.g., applying the value of the next wetter GEST), or any alternative way of ensuring conservativeness, must be demonstrated.

To ensure that carbon stocks are estimated in a way that is accurate, verifiable, transparent, and consistent across measurement periods, the project proponent must establish and document

[27] Typically, citations for sources of data used should include: the report or paper title, publisher, page numbers, publication date etc (or a detailed web address). If web-based reports are cited, hardcopies should be included as annexes in the project documentation if there is any likelihood such reports may not be permanently available.

clear standard operating procedures and procedures for ensuring data quality. At a minimum, these procedures must include:

- Comprehensive documentation of all field measurements carried out in the project area. This document must be detailed enough to allow replication of sampling in the event of staff turnover between monitoring periods.
- Training procedures for all persons involved in field measurement or data analysis. The scope and date of all training must be documented.
- A protocol for assessing the accuracy of plot measurements using a check cruise and a plan for correcting the inventory if errors are discovered.
- Protocols for assessing data for outliers, transcription errors, and consistency across measurement periods.
- Data sheets must be safely archived for the life of the project. Data stored in electronic formats must be backed up.

9.3.3 Expert judgment

Expert judgment on methodological choice and choice of input data and to fill gaps in the available data, to select data from a range of possible values or on uncertainty ranges is well established in the IPCC 2006 good practice guidance. Obtaining well-informed judgments from domain experts regarding best estimates and uncertainties of inputs to the quantification of emission reductions is an important aspect in various procedures throughout this methodology. Project proponents must use the guidance provided in Chapter 2, Volume 1 (Approaches to Data Collection), in particular, Section 2.2 and Annex 2A.1 of the IPCC 2006 Guidelines for National Greenhouse Gas Inventories.

9.3.4 Monitoring of project implementation

Information must be provided, and recorded in the project documentation to establish that:

a) The geographic position of the project boundary is recorded for all areas of land. The geographic coordinates of the project boundary (and any stratification or buffer zones inside the boundary) are established, recorded and archived. This can be achieved by field survey (e.g., using GPS), or by using georeferenced spatial data (e.g., maps, GIS datasets, orthorectified aerial photography or georeferenced remote sensing images).

   The above also applies to the recording of strata, including strata resulting from peatland fires in the project scenario (Section 8.3).

b) Commonly accepted principles of land use inventory and management are implemented such as the following:

   - Standard operating procedures (SOPs) and quality control/quality assurance (QA/QC) procedures for inventories including field data collection and data management must be applied. Use or adaptation of SOPs already applied in national land use monitoring, or available from published handbooks, or from the IPCC GPG LULUCF 2003, is recommended;

- Apply SOPs, especially, for actions likely to cause peat disturbances;
- The project plan, together with a record of the plan as actually implemented during the project must be available for validation or verification, as appropriate.

Continued compliance with the applicability conditions of this methodology must be ensured by monitoring that:

- Burning of biomass within the project boundary in the project scenario does not occur. Small and isolated events (with *de minimis* effects on GHG emissions'), although not permitted, do not fail the project.
- Peatland fires within the project boundary do not occur in the project scenario. If they occur as non-catastrophic events as defined in this methodology, they are accounted for by cancelling the *Fire Reduction Premium* for the entire project or the individual sub-project.
- Water leakage, if occurring, is limited to accidents that can be repaired (e.g., the breaching of a dam). Such accidents and their remediation must be monitored together with justifications that the effect has been temporal and insignificant and has not caused the dieback of woody vegetation in adjacent areas.
- N-fertilizers are not used within the project boundary in the project scenario.

The effectiveness of buffer zones must be demonstrated. This must be done using water level gauges or vegetation assessments (see Section 9.3.6 for procedures), or a combination of these.

a) If a buffer zone has been established, water level gauges must be installed at the boundary of the buffer zone (outer boundary if used against leakage, inner boundary if used against drainage activities outside the project area) and readings must be compared with the hydrological modeling results or expert judgment on which the establishment of the buffer zone was based. The number and spacing of water level gauges must be based on hydrological modeling or expert judgment. Alternatively, a GEST vegetation assessment must be performed in the buffer zone. Results for vegetation types adjacent to the project boundary are compared with the vegetation composition in the same area at project start.

b) In the case of an impermeable dam, to demonstrate its effectiveness, water level gauges must be located outside the dam (if used against leakage) or inside the dam (if used against effects of drainage outside the project boundary). Placing gauges outside the boundary may require agreements with adjacent landowners if the dam is located on the project boundary. Alternatively, a vegetation assessment must be performed in a strip adjacent to and outside the project boundary (leakage) or inside the boundary (outside drainage effects). The width of this strip is determined by the size of the area with homogeneous GEST characteristics nearest to the boundary. Results are compared with the vegetation composition in the same zone at project start.

c) In absence of a buffer zone or an impermeable dam (e.g., in case pump-drained systems are rewetted), water level gauges must be installed or vegetation assessed as described in (a) above, or the proponent must justify in the project documentation that such measurements can be omitted.

9.3.5 Stratification and sampling framework

Stratification of the Project Area into relatively homogeneous units can either increase the measuring precision without increasing the cost unduly, or reduce the cost without reducing measuring precision because of the lower variance within each homogeneous unit. Project proponents must present in the project documentation an *ex-ante* stratification of the Project Area or justify the lack of it. The number and boundaries of the strata defined *ex ante* may change during the project crediting period (*ex post*).

The *ex-post* stratification must be updated because of the following reasons:

- Unexpected disturbances occurring during the project crediting period (e.g., due to changes in the hydrology, fire, pests or disease outbreaks), affecting differently various parts of an originally homogeneous stratum;
- Management activities (forestry, agriculture, hydrology) that are implemented in a way that affects the existing stratification.

  Established strata may be merged if the reasons for their establishment have disappeared.

The sampling framework, including sample size, plot size, plot shape, and determination of plot location must be specified in the project documentation. Where changes in carbon stocks are to be monitored (i.e., in trees), permanent sampling plots are used, noting the following:

1) To determine the sample size and allocation among strata, this methodology uses the procedures in Section 9.3.5 and the latest version of the tool for the “Calculation of the number of sample plots for measurements within A/R CDM project activities”, approved by the CDM Executive Board. The targeted confidence interval must be 90% or 95%. Where a 90% confidence interval is adopted and the width of the confidence interval exceeds 20% of the estimated value or where a 95% confidence interval is adopted and the width of the confidence interval exceeds 30% of the estimated value, an appropriate confidence deduction must be applied, as outlined in Section 8.5.2.
2) In order to avoid bias, sample plots should be marked inconspicuously.
3) The sample plot size must be established according to common practice in forest and vegetation inventories.
4) To avoid subjective choice of plot locations, the permanent sample plots must be located either systematically with a random start or completely randomly inside each defined stratum. The geographical position (GPS coordinate), administrative location, stratum and stand, series number of each plot, as well as the procedure used for locating them

must be recorded and archived. The sampling plots are to be as evenly distributed as possible, where larger strata have more plots than smaller strata. However, remote areas and areas with poor accessibility may be excluded for the location of sampling plots. Such areas must be mapped as separate strata and for these strata accounting of carbon stocks in tree biomass in the project scenario is conservatively omitted (Section 8.2.2).

Guidance on plot size for GEST assessments is provided under "Assessing the spatial distribution of GESTs" in Section 9.3.6.

The choice of monitoring frequency must be justified in the project documentation.

9.3.6 Estimating GHG emissions on the basis of GESTs and water table depth

A GEST-indication system is based on a meta-analysis of published and other data of GHG fluxes (emissions or removals) in relation to site characteristics of a wide range of sites in a specific biogeographic and climatic region (Couwenberg *et al.*, 2011). For the analysis of GHG fluxes, only data on yearly net fluxes, based on year-round measurements or on sound model extrapolations are used. With respect to CO_2 fluxes, care has to be taken to include only net CO_2 balances (NEE or NEP) from reliable models using light and dark fluxes as input. The meta-analysis of data is used for the following:

- Classify vegetation data and GHG flux characteristics in a way that the distinguished vegetation types optimally indicate GHG fluxes;
- Develop regression models between GHG fluxes and mean annual water table depth (as this is the prime explanatory variable for annual GHG fluxes from peatland) in order to allow a triangular verification crosscheck between independent datasets: (i) flux data related to the vegetation types, (ii) flux data related to water table depths and (iii) vegetation types related to water table depths.

<u>Determining CO_2 and CH_4 emissions</u>

For project-specific flux values the project proponent may carry out direct measurements of GHG fluxes, such as closed chamber and eddy covariance measurements. Applied techniques must follow international standards of application as laid out in pertinent scientific literature (e.g., Matson & Harriss, 1995, Pattey *et al*. 2006, Alm *et al*. 2007, Evans *et al*. 2011).

<u>Determining GESTs</u>

GESTs can be classified and specified with respect to their GHG flux values using the following step-wise protocol for meta-analysis of collected data (cf. Couwenberg *et al.*, 2011):

1) Develop regression models between GHG fluxes and mean annual water table depth on the basis of all available data from the relevant biogeographic and climatic region;
2) Classify relevant vegetation types that are actually found and potentially expected in the region on the basis of plant species or species groups indicative for water table depth,

using for example the bio-indication data of Ellenberg *et al.* (1992) and Koska *et al.* (2001);

3) Compare the distinguished vegetation types with the vegetation data from sites in the relevant region for which reliable GHG flux data are available. If vegetation of a type is sufficiently similar (e.g., with respect to presence and absence of species groups (Koska, 2007; Koska *et al.* 2001); similarity is defined on the basis of floristic composition or plant functional types and expert judgment and must be justified) to vegetation for which the GHG flux values are reported in literature, the range of GHG values from literature is ascribed to the type;

4) The results of step 3 may be verified and refined by comparing the water table depth data (acquired from field observation, vegetation form indication (Koska *et al.* 2001) and/or Ellenberg values) of the sites used under Step 3 above with the regression models from Step 1 above to verify and refine the flux values found under Step 3 above. After verification and refinement of the flux values, the vegetation type is a GEST.

5) In case a distinguished vegetation type does not have sufficient similarity (see above) with vegetation described in GHG literature, use the mean annual water table depth data and the regression models to establish its preliminary flux values.

6) Optimize the GHG flux value of the vegetation type by expert judgment using the matrix of all distinguished vegetation types and taking into account the emission-relevant site characteristics of the vegetation type (incl. the proportion of shunt species in case mean water table depths are higher than 20 cm below surface; water table depth, soil reaction, C/N of the peat, type and intensity of land use) and the emission and site characteristics of related vegetation types. As soon as the GHG flux values of a type can be consistently and unequivocally defined, the type is considered a GEST (Table 3), independent from the deduced range of GHG fluxes. Later expansion of the GHG flux/vegetation dataset may lead to further refining the GESTs and to narrowing GHG flux ranges.

7) Flux values associated with vegetation types must comply with QA/QC requirements outlined in Section 9.3.2 and are subject to the uncertainty assessment. Where an uncertainty value is not known or cannot be simply calculated the project proponent must justify that a conservative value is used.

The results of this procedure must be described in the project documentation. An example of this can be found in Table 9.1 below.

Table 9.1: Example of GESTs Related to Water Table Depth Class and CH_4 and CO_2 Emission Values (after Couwenberg *et al.* 2008, 2011).

GEST	Typical/differentiating species	Water table depth class	CO_2 emission t CO_2e $ha^{-1}yr^{-1}$	CH_4 emission t CO_2e $ha^{-1}yr^{-1}$	Reference
Moist bog heath	*Calluna, Vaccinium myrt., Ledum + Dicranum scop., Pleurozium* (+ *Molinia*)	Moist	12.5	0	Couwenberg et al. 2008, 2011
Wet reeds and sedge fens	*Carex paniculata, Epilobium hirsutum, Lycopus, Lythrum, Berula erecta*	Wet	-4	12.5	Couwenberg et al. 2008, 2011

Water table depth classes refer to water supply: +: wetlands and aquatic habitats; -: non-hydric terrestrial habitats. They are characterised by: WLw: long-term median water table depth wet season; WLd: long term median water table depth dry season; and WD: water supply deficiency. Seasonally alternating wetness is indicated by a combination of different water table depth classes (e.g., 5+/4+ refers to a WLw within 5+ range and a WLd within 4+ range). Strongly alternating wetness is indicated by a tilde-sign (e.g., 3~ refers to a WLw within 4+ range and a WLd within 2+ range).

Class		Water table depth related to surface (+ above, - below)
7+	Upper sublitoral	WLm: +250 to +140 cm
6+	Lower eulitoral	WLm: +140 to +20 cm
5+	Wet (upper eulitoral)	WLm: +20 to 0 cm
4+	Very moist	WLm: 0 to -20 cm
3+	Moist	WLm: -20 to -45 cm
2+	Moderately moist	WLm: -45 to -80 cm
2-	Moderately dry	WD: < 60 l/m²
3-	Dry	WD: 60 – 100 l/m²
4-	Very dry	WD: 100 – 140 l/m²
5-	Extremely dry	WD: > 140 l/m²

Assessing the spatial distribution of GESTs

For assessing the spatial distribution of GESTs in the field, project proponents must apply the following procedure:

1) Map units of more or less homogenous vegetation using common approaches (incl. remote sensing, see Box) and specify mapping resolution. Use units larger than 3000 m^2. Include areas < 3000 m^2 with deviating vegetation in an adjacent mapping unit, when the water table depth is identical and the soil relief differences smaller than 1 dm. Map strongly deviant units (much higher, much lower, forested, open spots in forest) > 1000 m^2 but < 3000 m^2 separately. Include deviant areas < 1000 m^2 in the adjacent mapping unit to which it is most related.

2) Map vegetation units < 3000 m^2 with soil relief differences of more than 1 decimeter (fine-scaled peat extraction sites, string/flark and hummock-hollow complexes) to mosaic mapping units > 3000 m^2. Describe their relief pattern (i.e. proportion, extent and height of various elements).

3) Assess within each mapping unit the cover of the living parts of “shunt species” (see Box) in five cover classes: 0-20%, 20-40%, 40-60%, 60-80%, 80-100%.

4) Mark the borders of the mapping units with GPS waypoints or track-routes or depict borders directly on a topographical map or aerial picture (with GPS reference points).

5) Record relevés (5 m × 5 m) of characteristic homogenous vegetation in each mapping unit to facilitate later (a posteriori) identification of the GESTs.

6) Assign the herb layer of shrub or tree-dominated peatland to non-forested vegetations types.

This procedure must be applied for both the pre-project spatial distribution of GESTs and monitoring. When monitoring, assess whether the range of GESTs with their specific GHG emission levels as obtained in Section 8.1.3.1sufficiently covers the vegetation types expected in the project scenario. If not, expand the system using the same procedure by collecting more literature or field data

Shunt species

Shunt species are species with aerenchyma (open stem and root tissue) that pump air into the rhizosphere and transport methane from the anaerobic soil layer directly into the atmosphere. As a consequence, an area with many shunt species may have a two times higher methane emission than other areas with a similar water table depth. Important shunt species are: *Blysmus* species, *Bolboschoenus* species, *Carex* species (tall and small sedges), *Cladium mariscus*, *Eleocharis* species, *Eriophorum angustifolium*, *Eriophorum vaginatum*, *Juncus* species, *Scheuchzeria palustris*, *Schoenoplectus* species, *Scirpus* species.

Vegetation mapping with high spatial resolution satellite imagery, for example:

- Use satellite imagery with a minimum spatial resolution of 5 m × 5 m and a minimum of four spectral channels, which includes visible and at least one infrared band.
- Derive the mapping units by vegetation indexes analysis or a simple unsupervised classification.

- Select in every mapping unit three random points for vegetation analysis (e.g., ISODATA classification).
- In each clearly distinguished mapping unit select three centrally located points for vegetation analysis.
- Visit these points and record representative vegetation relevés (using high accuracy GPS devices and record water table depth).
- Conduct a supervised classification (e.g., a maximum likelihood classification of 90%), minimum distance classifier or spectral angle mapper, if necessary include vegetation indexes.
- To improve the classification result, high quality geo-referencing is favourable and training areas can be added/removed on the base of site knowledge; the training areas or regions of interest based on groundtruthing data should be outlined on minimum 5 pixels
- Relate the classes to vegetation forms or additional vegetation types based on relevés and site knowledge.
- Conduct an accuracy assessment, by checking the classification result via visiting additional ground control points. These additional points must be selected so that each class is represented by more than one point. Accuracy must be at least 60%, any activities to increase the accuracy are recommended.

Deriving time series of GEST development for each stratum for the entire project crediting period

Predict (*ex ante*), based on vegetation succession schemes in drained and rewetted peatlands from scientific literature or expert judgment, or monitor GESTs (*ex post*), for each stratum and for the entire project crediting period, the development of GESTs over time by defining a time series of GESTs, with time steps of a reasonable time period (e.g., 5 years) to allow for the inherent discrete character of the GESTs.

Determining annual GHG emissions per stratum for the entire project crediting period

Obtain annual GHG emissions per stratum by extrapolation between the typical emissions of two subsequent GESTs in a time series. Extrapolation can be linear, skewed, or conservative. If the chosen interpolation method is not inherently conservative, the project proponent must provide conclusive argumentation why the chosen method would apply.

For each stratum, the annual results can be reported in the formatting of Table 9.2. Italics indicate interpolated values.

Table 9.2: Time Series of Emissions from GESTs.

Year	Stratum 1	Total emissions t $CO_2e\ yr^{-1}$
1	GEST1	15
2		*16*
3		*17*

4		*18*
5	GEST2	19
…		…
…		…
15	GEST3 | GEST4	22*
…		…

* Area-weighted average of GEST 3 and GEST 4 emissions. Stratum 1 is subdivided into 1a and 1b.

For areas for which the vegetation composition does not provide a clear indication of GHG emissions (bare peat, transient phases of vegetation development after rewetting) water table depth measurements must be used as additional input to assess GHG fluxes. However, project proponents may also opt to choose water table depth as a proxy for the entire project area.

Strata can be defined on the basis of (amongst others) water table depth (e.g., at 0 cm defining a level of zero emissions, a deep water table depth defining the high end of emissions, and arbitrary levels in between, or expected changes in these). Water table depths or water table depth classes (e.g., 0-10 cm, 11-20 cm, etc.) can be used, depending on data availability.

Water table depth measurements can be continuous with data loggers and using min-max devices (Bragg *et al*., 1994) or simple water level gauges.

Normally, the vegetation mapping can be conducted during the entire vegetation period. The water table depth measurements must be done at least throughout the seasons (spring to winter) to capture seasonal variation. The frequency of monitoring vegetation changes must be based on expert judgment, taking into account expected and observed changes in vegetation composition upon rewetting. A recommended monitoring schedule for temperate climate zones is provided below:

- Mapping vegetation types: before rewetting, 2nd year after rewetting, 5th year after rewetting, then every 5th year after rewetting
- Monitoring water table depth: continuously from 1 year before rewetting, to the end of the project crediting period.

9.3.7 Monitoring of fire events in the project scenario

As laid out in Section 8.3, if peatland rewetting and a best-practices fire management have been implemented, peat fires occurring in the project scenario can be assumed to be catastrophic events. If such fires occur, the project proponent must demonstrate that rewetting and fire management have been carried out as proposed at validation. Peat losses associated with such fires must be added to the *ex-ante* estimate of peat loss in the project scenario as they may affect the number of eligible credits (Section 5.2 – Peatland areas eligible for carbon crediting). The assessment of peat losses must follow the fire-specific procedures and criteria used to derive $Rate_{peatloss\text{-}BSL}$ (Section 9.1).

2 SUMMARY DESCRIPTION OF THE METHODOLOGY

Additionality and Crediting Method	
Additionality	Project Method
Crediting Baseline	Project Method

This methodology is applicable to project activities that reduce greenhouse gas (GHG) emissions from mosaic unplanned deforestation and forest degradation, and that enhance GHG sequestration through afforestation, reforestation and revegetation (ARR) activities. This methodology was developed with the intended use in India, but is globally applicable.

Mosaic degradation of forest lands may be the result of many drivers, such as unsustainable fuelwood extraction and uncontrolled grazing. Reduction of these activities is important since their continuation may lead to deforestation.

This methodology was developed with a focus on the specific drivers listed in Table 1 below. For the purposes of this methodology, these drivers are categorized as either a deforestation or forest degradation activity.

Table 1: List of Drivers Considered

Drivers and activities considered under this methodology	Deforestation or degradation
Unsustainable extraction of fuel wood	Degradation
Unsustainable extraction of non-timber forest produce (NTFP)	Degradation
Unplanned timber harvesting	Degradation
Uncontrolled grazing and fodder collection	Degradation
Anthropogenic forest fire	Deforestation
Unplanned mining and quarrying	Deforestation
Expansion of subsistence agriculture by conversion of forest lands	Deforestation
Encroachment	Deforestation

The drivers listed in Table 1 were identified, based on observed practices in India,[1] as the most impactful in terms of their contribution to emissions from deforestation and degradation.

[1] Drivers and localized agents that are active in forest areas facing pressure were shortlisted based on literature review, focal group interviews and stakeholder consultation. Different landscapes in India were chosen as pilot study sites for analyzing driver dynamics. Choosing Indian sites for the study was important due to the following:

The main elements of this methodology include:

- A project method for demonstrating both additionality and the crediting baseline.
- Separate quantification methods for REDD and ARR project activities.
- An optional method for monitoring the project area with the help of local communities.
- Options to use secondary data from sources already available, such as censuses, working plans, and existing participatory rural appraisals (PRAs)[2] to form detailed references of active drivers and their physical extent.

3 DEFINITIONS & ACRONYMS

3.1 Definitions

In addition to the definitions set out in VCS document *Program Definitions*, the following definitions apply to this methodology:

Activity-shifting Leakage
Leakage caused by the application of conservation practices in the project area which leads to undesirable and unintended movement of Drivers of Forest Change (DoFC) outside the project area, leading to GHG emissions due to deforestation and forest degradation in those other areas. Where the shifting of activities increases the rate of DoFC, the related land use change, carbon stock/density changes and non-CO_2 emissions must be estimated and accounted for as leakage.

Anthropogenic Forest Fires
Forest fires which originate due to human activity

Avoiding Planned Deforestation and/or Degradation (APDD)
Activities that stop planned deforestation and/or degradation of forest lands

Avoiding Unplanned Deforestation and/or Degradation (AUDD)
Activities that stop unplanned deforestation and/or degradation of forest lands

---

1) India, having a large geographical area, a forest cover of 21.34% (ISFR 2015 http://fsi.nic.in/isfr-2015/isfr-2015-executive-summary.pdf),and more than 300 million forest dependent people (including around 87 million tribal peoples), is an ideal candidate to study mosaic deforestation and degradation of forest lands under varied drivers.
2) Management regime and land tenure is different from state to state, and so the country is a good candidate to study jurisdictional aspects of baseline development.
3) No large scale deforestation has occurred in recent years, and so few cases of frontier deforestation are observed. This helps in better understanding the dynamics of deforestation and degradation caused due to drivers in mosaic deforestation and degradation.

[2] Note that existing PRAs can be used only for data comparison where a new PRA has been conducted.

Baseline Validation Period

The 10 year period for which the baseline remains valid. The baseline must be reassessed every 10 years throughout the project crediting period in accordance with the VCS rules.

Deforestation

Direct human-induced conversion of forest land to non-forest land. Deforestation implies the long-term or permanent loss of forest cover. For this methodology, the change in land use from forest land to non-forest land must not be less than three years.

Degradation

The persistent reduction of canopy cover and/or carbon stocks in a forest due to human activities such as animal grazing, fuelwood extraction, timber removal or other such activities, but that does not result in the conversion of forest to non-forest land, and falls under the *IPCC 2003 Good Practice Guidance* land category of *forest remaining forest*. For this methodology, continued loss of carbon stock from forest land for at least three years qualifies as degradation.

Drivers of Forest Change (DoFC)

Activities that lead to losses in forest carbon

Historical Reference Period

The period during which the selected reference region transitions from forest land to non-forest land, or in the case of degradation, the period during which degradation occurs

Land Use and Land Cover (LULC) Classes

The six LULC classes as specified by IPCC, or LULC classes which the host country has specified, provided that all the land classes under IPCC are covered by the latter

Leakage Area

An area outside the project area to where the drivers of deforestation and degradation of forest lands are displaced in the case of REDD activities.

Leakage Management Zone (LMZ)

An area earmarked as an area which is intended to reduce leakage

Logging Slash

Dead wood residues (including foliage) left on the forest floor after timber removal

Market Leakage

Leakage caused by conservation practices inside the project area such that there is impact on the supply chain of forest products which result in a shift of production of forest product elsewhere to fulfill demand

Minimum Mapping Unit (MMU)
The minimum unit that is used in classification and RS analysis, and is fixed as 1 ha

Project Area (PA)
The geographical area where REDD activities (with or without ARR activities) are implemented. ARR and REDD areas must be separately mapped and must not share the same area. The project area must be forest land for a minimum of 10 years prior to the project start date.

Reference Region (RR)
The region from which the historical trends of changes in forest land are modeled. From these trends, the change that is expected to occur within the project area in the baseline scenario is predicted.

3.2 Acronyms

ACoGS	Avoided Conversion of Grasslands and Shrublands
AFOLU	Agriculture, Forestry and Other Land Use
AGB	Above Ground Biomass
BGB	Below Ground Biomass
CIFOR	Center for International Forestry Research
DBH	Diameter at Breast Height
FGD	Focal Group Discussion
GOFC-GOLD	Global Observation of Forest and Land Cover Dynamics
IFM	Improved Forest Management
KML	Keyhole Markup Language
LIDAR	Light Detection and Ranging
LMZ	Leakage Management Zone
LULC	Land Use Land Cover
NTFP	Non Timber Forest Produce
PA	Project Area
PRA	Participatory Rural Appraisal
RR	Reference Region
RS	Remote Sensing
SAR	Synthetic Aperture Radar
SOC	Soil Organic Carbon
SOP	Standard Operating Procedures

4 APPLICABILITY CONDITIONS

This methodology is globally applicable under the following conditions:

1) The project activities include AUDD[3] or a combination of AUDD and ARR.
2) The project area must meet the definition of forest land for at least 10 years prior to the start date of any REDD activities.
3) The project area must not be forest land for at least 10 years prior to the start date of any ARR activities and must not convert native ecosystems.
4) Biofuel crop production is allowed in ARR activities.

This methodology is not applicable under the following conditions:

1) The project activities include APDD.
2) The project activities only include ARR.
3) ARR activities displace more than 50 percent of agricultural lands from the project area.
4) The project activities take place on wetlands or peatlands.
5) The project activities include ACoGS.

5 PROJECT BOUNDARY

5.1 Reference Region

A reference region (RR) must be identified and analyzed in order to effectively capture the trends of deforestation and degradation of forest lands that would occur in the baseline scenario within the project area (PA). There are two approaches to assess the historical rate of deforestation and forest degradation within the reference region. Approach 2 may be employed only when the project area is equal to, or is less than, 1000 ha and in proximity to the reference region. In all other cases, approach 1 must be applied. Further requirements for the RR and PA are as follows:

- The area of the RR must not be less than that of the PA.
- The RR need not share a boundary with the PA.
- The RR need not be contiguous, and may be formed by distinct parcels.
- REDD components and ARR components of the project must be distinctly mapped.

[3] AUDD activities will be referred to as REDD activities for the remainder of the methodology.

Approach 1: When selecting a RR, the project proponent must satisfy all points of comparison between the RR and PA mentioned in Table 2 below.

Table 2: Comparison between Project Area and Reference Region

Factor	Points of Comparison
Forest types and landscape factors	The forest types and landscape factors within the RR must be similar to the forest types and landscape factors within the PA. With respect to forest types, a list of all the forest types within the PA and RR must be prepared, and the RR must be comparable in proportion (within ±20%) to those present in the PA. The forest classification (e.g., revised Champion and Seth Forest Classification by ICFRE)[4] used in the host country may be used for this exercise. Any forest type that composes at least 5% of the PA must be present within the RR, and any forest type composing more than 5% of the RR that is not present in the PA must be removed from any LULC analysis. With respect to landscape factors, a comparison of elevation, slope, and climactic conditions (e.g., temperature and rainfall) must be undertaken between the PA and RR, and each factor must be demonstrated to be similar in proportion.
Drivers	The types of prevalent drivers (e.g., extraction of fuel wood and other drivers listed in Table 1) must be the same between the RR and PA. To determine this, two lists of all possible drivers must be prepared, one for RR and one for PA. All the drivers in the respective region are marked and selected for comparison. All the drivers which are present in the RR, but absent in the PA must be identified, and the areas which are affected by such drivers must be identified. RR is again modified by removing such areas, and conducting the exercise once again until all such areas are removed from the RR. A similar comparison of agents of forest change also must be conducted after finalizing the list of drivers. Any agent not active in the PA must be excluded from RR. The requirements for analysis of drivers of forest change (DoFC) are discussed more in detail in Section 8.1.7 below.
Land tenure and management	The land tenure system and management practices

[4] This is just an indicative method, where the Indian case is taken as an example. Every country will have the freedom to choose the forest classification that they want to use.

Factor	Points of Comparison
practices	prevalent in the RR must be demonstrated to be similar to the land tenure system and management practices in the PA, as demonstrated through reference to peer-reviewed literature, reports, or expert opinion. Such must be demonstrated even if RR does not share a boundary with the PA, and is comprised of discrete parcels. Therefore, RR and PA may not be subject to two completely different land tenure and management practices, either partially or for the whole area.
Policies and regulations	Policies and regulations having an impact on land-use change patterns within the RR and the PA must be of the same type, or have an equivalent effect, taking into account the current level of enforcement.
Population factors and transportation infrastructure	Where navigable rivers are present in the PA, navigable river/stream density must be similar in proportion in the RR. In addition, proximity and/or potential of the proximity to the transportation infrastructure (e.g., roads) must be similar between the RR at the start of the historical reference period and PA. Finally, proximity to population centers with similar population density must also be similar in proportion between the RR at the start of the historical reference period and PA.

If no area exists within the country that satisfies all points of comparison, the project proponent must justify use of a reference region that satisfies the requirements for forest type and drivers, and is justified to be conservative for other points of comparison, or a conservative deduction is applied for uncertainty when analyzing LULC change.

Examples of different spatial configurations of the RR and PA are given in Figures 1, 2 and 3 below.

Figure 1: Project Area Inside the Reference Region

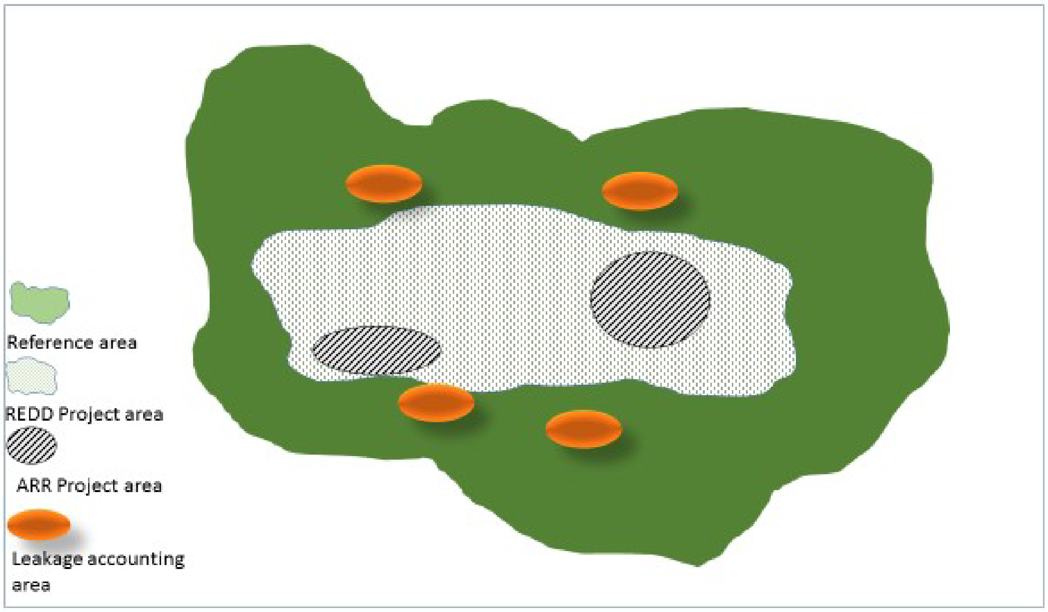

Figure 2: Project Area and Reference Region Not Sharing Boundary

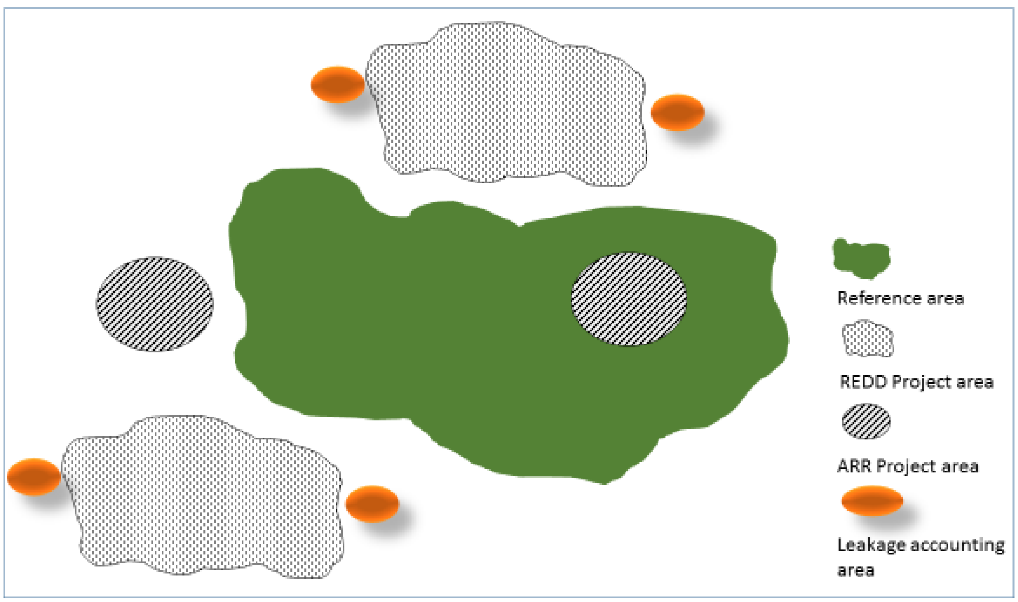

Figure 3: Discrete Parcels of Project Area and Reference Region

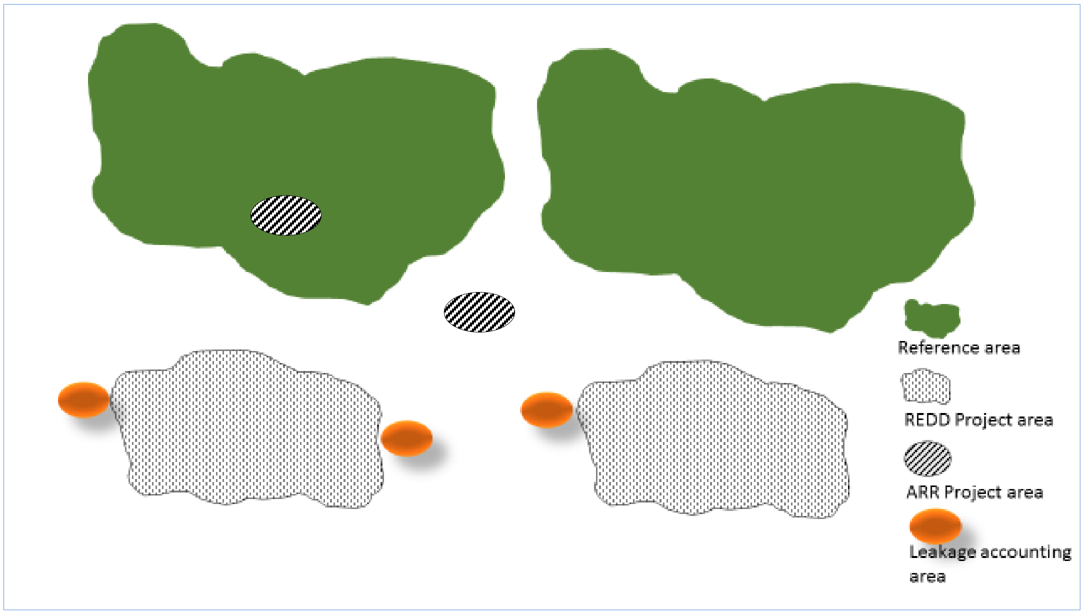


Approach 2: This approach is applicable only under the following conditions:

1) Each project parcel is demonstrated to be equal to, or less than, 1000 ha.

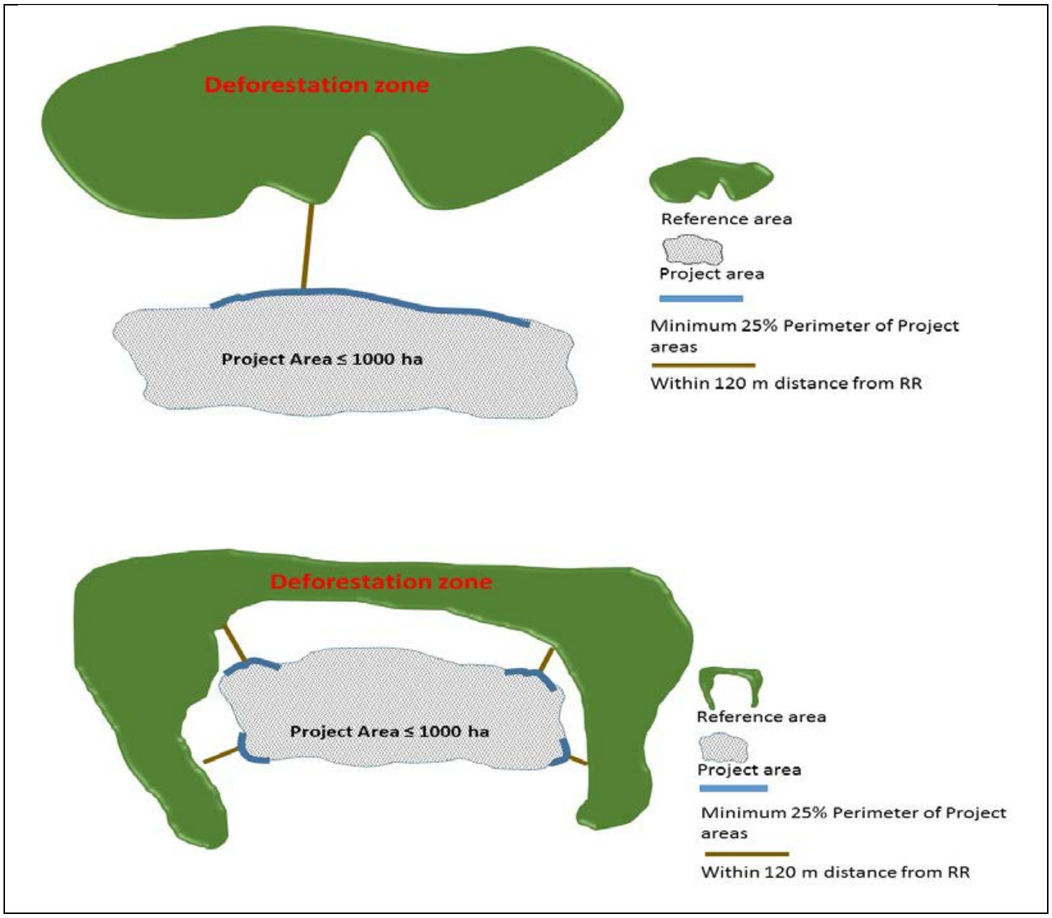
2) Project parcels must lie within 120 meters of an anthropogenic deforested area where it can be demonstrated that such deforestation occurred within 10 years prior to the project start date.

3) It is demonstrated that at least 25 percent of the perimeter of the project parcel lies within 120 meters of the deforested area identified (2) above.

The above must be demonstrated by applying different social and geographical survey tools and techniques, which include, *inter alia*, land survey reports/records, PRA, FGD, official LULC records and revenue department records. Peer reviewed and published papers may be referenced where they were published within 10 years prior to the project start date. Scalable maps that clearly demarcate project areas and reference region(s) must be available at the time of validation.

It is anticipated that if immediate intervention activities are not initiated in approach 2 scenarios, that the agents active in the reference region will imminently affect the project parcel. Examples of such configurations are shown in Figure 4 below.'

Figure 4: Approach 2 Scenarios



5.2 Leakage Management Zone (LMZ)

The LMZ is the area designated to manage potential leakage. An LMZ must be developed for all project areas where the same amount of goods and services from forests will be extracted in the project scenario as compared to the baseline scenario. It must be established that LMZs are within the maximum distance the agent is willing to travel to avail the specific goods and services that has been availed in the baseline scenario. The maximum distance the agent is willing to travel may be ascertained by using tools such as PRA, RRA, key informant interview, FGD, survey and expert opinion.

Where an LMZ is not developed, the project proponent must map the sources from where these goods and services will be availed/procured for the first 10 years from the start date of the project activity. These sources must be considered as potential points of leakage, and must be spatially mapped. This must be updated every 10 years along with the baseline reassessment. In those instances where there is a decrease in the goods and services availed due to project activities, such LMZs are not mandated[5].

5.3 Carbon Pools

The carbon pools included in or excluded from the project boundary are shown in Tables 3 and 4 below.

Table 3: Carbon Pools Included In or Excluded From the Project Boundary for REDD Activities

REDD Activity	Carbon Pool	Included?	Justification/Explanation
REDD with annual crop as the land cover in the baseline scenario	Aboveground tree biomass	Yes	Carbon stock will increase and is one of the major carbon pools
	Aboveground non-tree Biomass	Optional	May be conservatively excluded
	Below ground biomass	Optional	May be conservatively excluded
	Dead wood	Optional	May be conservatively excluded
	Litter	No	Excluded as per the VCS *AFOLU Requirements*
	Wood products	Yes	Major carbon pool affected by the project activities and must be included
	Soil Organic carbon	Optional	May be conservatively excluded
REDD with pasture grass as the land cover in the baseline scenario	Aboveground tree biomass	Yes	Carbon stocks will increase and is one of the major carbon pools
	Aboveground non-tree Biomass	Optional	May be conservatively excluded
	Below ground biomass	Optional	May be conservatively excluded
	Dead wood	Optional	May be conservatively

[5] For example, if improved cook stoves are designed as intervention, then there is a drop in the resources used from forests. LMZ is still desirable, but not mandated in such instances.

			excluded
	Litter	No	Excluded as per the VCS *AFOLU Requirements*
	Wood products	Yes	Major carbon pool affected by the project activities and must be included
	Soil Organic carbon	No	Excluded as per the VCS *AFOLU Requirements*
REDD with perennial tree crop as the land cover in the baseline scenario	Aboveground tree biomass	Yes	Carbon stock will increase and is one of the major carbon pools
	Aboveground non-tree Biomass	Yes	May be conservatively excluded
	Below ground biomass	Optional	May be conservatively excluded
	Dead wood	Optional	May be conservatively excluded
	Litter	No	Excluded as per the VCS *AFOLU Requirements*
	Wood products	Yes	Major carbon pool affected by the project activities and must be included
	Soil organic carbon	No	Excluded as per the VCS *AFOLU Requirements*

Table 4: Carbon Pools Included In or Excluded From the Project Boundary for ARR Activities

ARR	Included?	Justification/Explanation
Aboveground woody biomass	Yes	One of the major carbon pools
Aboveground non-woody biomass	Optional	May be conservatively excluded
Below ground biomass	Yes	One of the major carbon pools
Dead wood	Optional	May be conservatively excluded
Litter	Optional	May be conservatively excluded
Wood products	Optional	May be conservatively excluded

Soil Organic Carbon	Optional	May be conservatively excluded

Carbon pools may be excluded if they are determined to be *de minimis*. To determine if a carbon pool is *de minimis*, the project proponent may use peer reviewed literature, or the latest version of CDM tool *Tool for testing significance of GHG emissions in A/R CDM*, or use primary data collected from the project site or reference site(s).

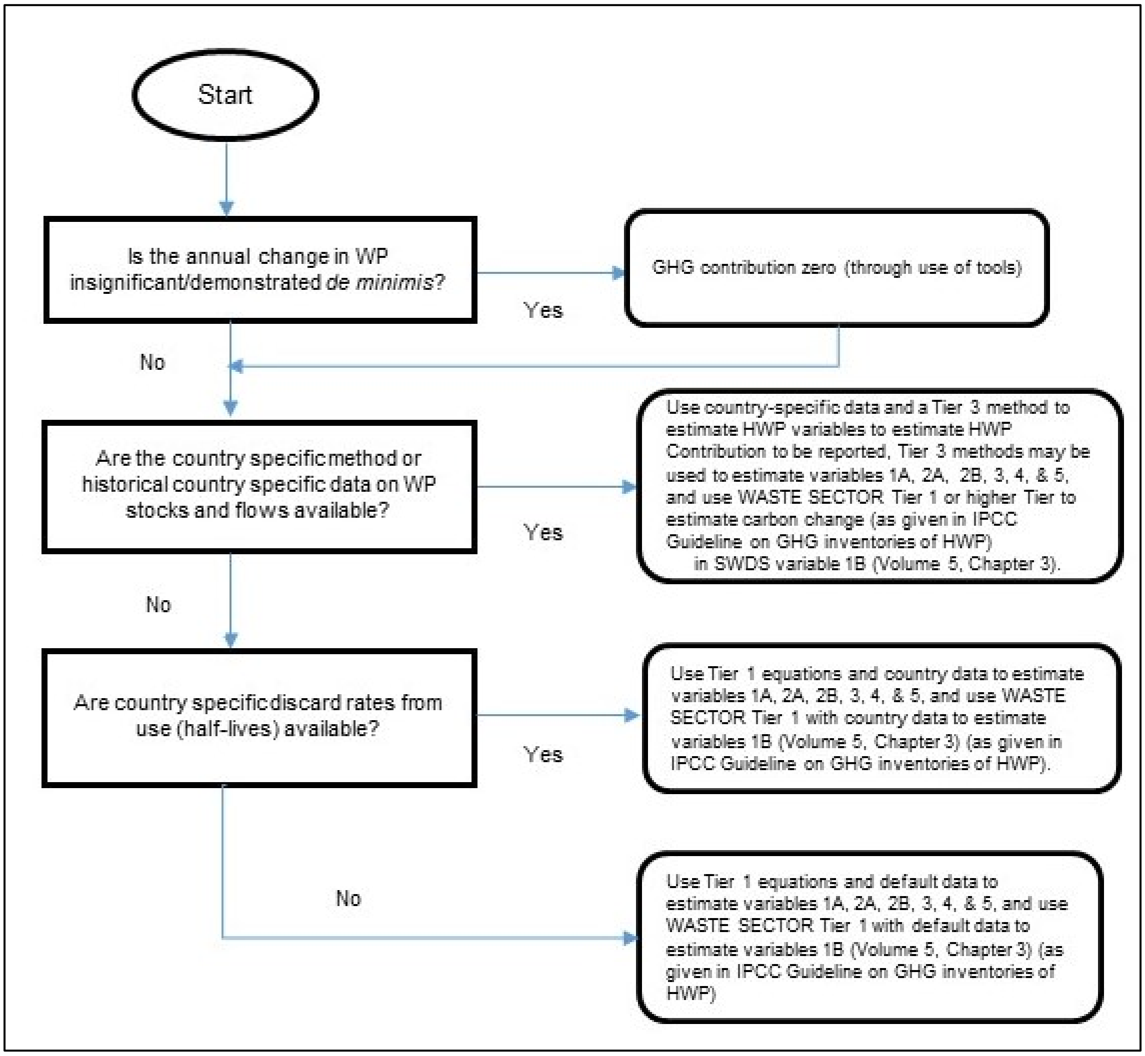
When below ground biomass and dead wood carbon pools are included as part of the project boundary, dead wood must be modeled using a 10- year linear decay function and soil carbon loss must be modeled based upon a 20-year linear decay function, taking into account the depth of affected soil layers and the total portion of the pool that would have been lost and affected.

When wood products are included, carbon loss must be modelled as follows:

- For short-term wood products and wood waste (i.e., decay within 3 years), all carbon must be assumed to be lost immediately.
- For medium-term wood products (i.e., decay between 3 and 100 years), a 20-year linear decay function must be applied.
- For long-term wood products that are considered permanent (i.e., carbon is stored for 100 years or more), no carbon released may be considered.

A decision tree for determining whether wood product pools must be accounted for is described in Figure 5 below and equations for calculating wood products may be derived from *IPCC Guideline on GHG Inventories of Harvested Wood Products*.

Figure 5 : Decision Tree of Reporting Wood Products[6]



5.4 GHG Sources

The greenhouse gases included in or excluded from the project boundary are shown in Table 5 below.

Table 4: GHG Sources Included In or Excluded From the Project Boundary

Source		Gas	Included?	Justification/Explanation
Baseline	Baseline Deforestation and Forest Degradation	CO_2	Yes	Emissions are related to changes in carbon pools.
		CH_4	Yes	Included only in the case of certain intervention activities such as cook stove and fuel efficiency activities

[6] Adapted from IPCC Guideline on GHG Inventories of HWP

Source		Gas	Included?	Justification/Explanation
				(CFE). In the baseline scenario, if biomass is burnt during land preparation in the case of ARR, CH_4 is included. In the baseline scenario, if grazing and animal management is involved, CH_4 is not included for reasons of conservativeness.
		N_2O	Yes	Included where cook stove and fuel efficiency activities (CFE) are involved. If biomass is burnt in the baseline or project scenarios, N_2O is included. If the baseline scenario involves application of fertilizers, N_2O is not included for reasons of conservativeness.
	Baseline ARR	CO_2	Yes	Emissions are related to changes in carbon pools.
		CH_4	No	Emissions are expected to be negligible and are therefore excluded.
		N_2O	No	Emissions are expected to be negligible and are therefore excluded.
Project	Biomass burning from unplanned large and small scale fires	CO_2	No	Emissions are excluded as they are a part of the changes in carbon pools.
		CH_4	Yes	CH_4 emissions of burning woody biomass from unplanned fires must be included. If the fires are catastrophic, CH_4 emissions must be estimated and demonstrated negligible, or otherwise accounted for.
		N_2O	Yes	N_2O emissions of burning woody biomass from unplanned fires are to be accounted. If the fires are catastrophic, N_2O emissions must be estimated and demonstrated negligible, or otherwise accounted

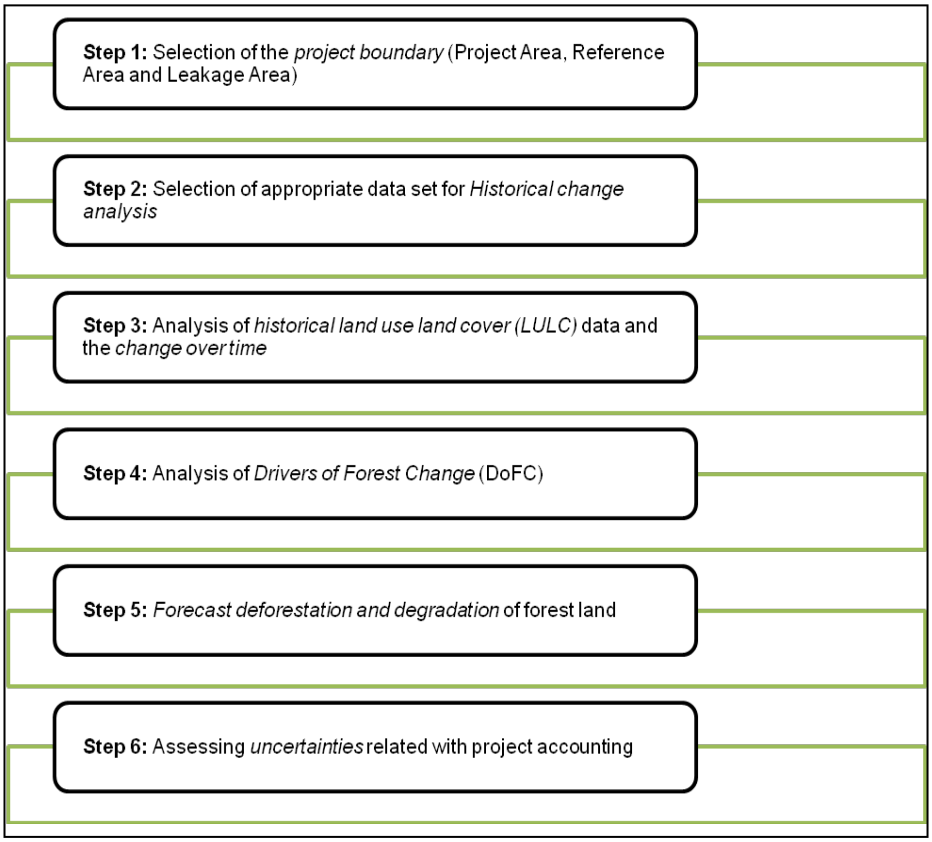
Source		Gas	Included?	Justification/Explanation
				for.
	Fossil fuel used during operations	CO_2	No	Emissions from fossil fuel combustion is considered *de minimis* for REDD and ARR, and is therefore excluded.
		CH_4	No	Insignificant
		N_2O	No	Insignificant
	Removal of woody biomass during assisted natural regeneration (ANR and ARR) activities	CO_2	Yes	Emissions related to changes in carbon pools are taken into account.
		CH_4	Yes	CH_4 emissions from removal of woody biomass are significant when fire is used in preparing the land for ANR activities.
		N_2O	No	N_2O emissions from burning woody biomass during ANR activities are assumed negligible and are therefore conservatively excluded.
	Fertilizer used during enrichment planting for assisting natural regeneration and ARR	CO_2	No	Assumed negligible
		CH_4	No	Assumed negligible
		N_2O	No	Assumed negligible
	Increased fertilizer use	CO_2	No	Not applicable
		CH_4	No	Not applicable
		N_2O	No	N2O emissions related to increased fertilizer use are *de minimis*.

6 BASELINE SCENARIO

The baseline scenario for this methodology is the historic and/or continued LULC and the changes in associated carbon stocks in all selected carbon pools within the project boundary. This is the case for both REDD and ARR components of the project. A step-by-step procedure for determining the baseline scenario is given below in Figure 6 below. Each step is expanded upon in Section 8.

Where a jurisdictional baseline has been developed and reference emission levels have been published by an appropriate entity (e.g., national or sub-national government agencies), the available jurisdictional baseline data must inform the development of the project-specific baseline.

Figure 6: Procedure to Determine Baseline Scenario and Emissions



The sources and sinks of the identified baseline scenario must be determined ex-ante for each year in the baseline validation period. Reassessment of the baseline must be conducted as per the VCS rules.

7 ADDITIONALITY

To demonstrate additionality, the project proponent must apply the steps given below:

Step 1: Regulatory Surplus

Project proponents must demonstrate regulatory surplus in accordance with the rules and requirements regarding regulatory surplus set out in latest version of the *VCS Standard*.

Step 2: VT0001 AFOLU Additionality Tool

After ensuring that the project meets the conditions of regulatory surplus, the project proponent must determine additionality by applying the latest version of VCS tool *VT0001 Tool for the Demonstration and Assessment of Additionality in VCS AFOLU Project Activities*.

8 QUANTIFICATION OF GHG EMISSION REDUCTIONS AND REMOVALS

8.1 Baseline Emissions (BE)

Baseline emissions include all emissions that would have happened in the project area in the absence of the implementation of the project. This is the case for both REDD and ARR components of the project. Baseline emissions are quantified based on the requirements in the sections that follow.

8.1.1 Select Project Area

The project area must be selected and clearly defined. The project boundary must not be finalized until due consideration of inputs from local stakeholder consultations have been taken into account.

The project area may coincide with a combination of natural boundaries and geopolitical or administrative boundaries (e.g., forest management and administration units such as beat boundaries, range boundaries, or revenue administration boundaries such as revenue districts). This will assist the management of projects and boundaries, and avoid duplication of boundaries. Discrete parcels of the project area are permitted.

8.1.2 Select Reference Region

The reference region must meet the conditions detailed in Section 5.1 above. The Land Use Land Cover (LULC) changes within the reference region are analyzed to develop the baseline of the project area. It must be demonstrated that the drivers causing changes in forest lands within the reference region are also active in the project area. The same reference region used for REDD activities must also be used to validate the baseline of any ARR activities.

8.1.3 Select Data Set for Historical Change Analysis

Appropriate data sets are to be selected for analyzing historical change in the reference region. The selected datasets must be of the same season, or of the same expected phenological variations in order to maintain uniformity.

Data sets must meet the following requirements:

- The change analysis must start no more than 30 years prior to the project start date.
- The change analysis must start no less than 10 years before the project start date.
- The change analysis must include at least 3 points to consider the historical LULC change analysis.
- The time points must be at least 4 years apart.
- At least one dataset must be within 2 years of the project start date.

The time horizon of the change analysis must be selected after taking into consideration all local, provincial, and national policies, laws, and trends that may have a general impact on forest carbon.

During validation, special care must be taken by the VVB to assess that the time horizon was not artificially expanded to account for more changes in carbon stocks. This may be done by analyzing the detailed policy changes and impact assessment that the project proponent must conduct and present to the VVB.

8.1.4 Land Use Land Cover Stratification Scheme

The project proponent must identify and describe the land-use and land-cover (LULC) strata present in the reference region at the project start date. The sampling and stratification strategy must follow regional/national strategies, or one that is in line with IPCC and international guidelines. Stratification must consider LULC classification as per the national classification scheme, and should consider all six IPCC classes (forest, cropland, grassland, wetlands, settlements, and other land). All forest types within the project area must also be considered. Any other significant sub-strata must be considered based on established scientific principles.

Forest land must therefore be further stratified based on forest types and density. This methodology allows the project proponent the use of nationally accepted canopy density classes with proper justifications. These classes may be further optionally subdivided based on spatial and spectral classification technique as found suitable by the project proponent.

Non-forest land may be further stratified in strata representing different non-forest classes. IPCC land classes used for national GHG inventories may be used to define such classes. However, where appropriate, additional or different sub-classes may be specified. Croplands may be further classified into smaller strata, as it is possible that cropping systems/plantations and associated practices directly or indirectly act as drivers of deforestation and forest degradation. This will provide for loss of forest carbon in each such stratum during the transition from forest lands. However, such a classification is not deemed mandatory.

The description of a LULC class must include criteria and thresholds that are relevant for the discrimination of that class from all other classes. Such criteria may include different kinds of information such as elevation above mean sea level, aspect, soil type, distance to roads and villages, and forest management category. Land with temporary unstocking of forest will not be considered under this methodology.

The minimum mapping unit (MMU) must be equal to, or less than, 1 ha.

8.1.5 Geo-spatial Analysis and Techniques

The stratification of forest and non-forest components is achieved using either digital classification algorithms such as maximum likelihood, decision trees, knowledge classifier, support vector machines or nationally approved forest/non-forest maps. The stratification approach also allows the project proponent to generate forest/non-forest masks using different vegetation indices and classification algorithms to ease the image classification process (P. Bholanatha, K. Cort, 2015) and (R. Suraj Reddy, 2014[7]).

The final classification map must include a minimum of six IPCC LULC classes to quantify deforestation. In case of heterogeneous forest types in the reference area, the classified map must also contain major forest types available in the landscape (see detailed workflow in Figure 7 below). The project proponent may use the existing administrative forest/non-forest boundaries or land use dynamics studies in or around the landscape to improve classification accuracy. The methodology also allows the project proponent to use any nationally or sub-nationally approved data. In such cases, further classification by the project proponent is not required.

8.1.5.1 Vegetation Index Model

A vegetation index model must be determined. The model must be based on satellite derived temporal vegetation indices images. Using these indices-based images, a vegetation fraction map or forest canopy density must be generated using spectral un-mixing or machine learning algorithms (Matricardi et al 2010).

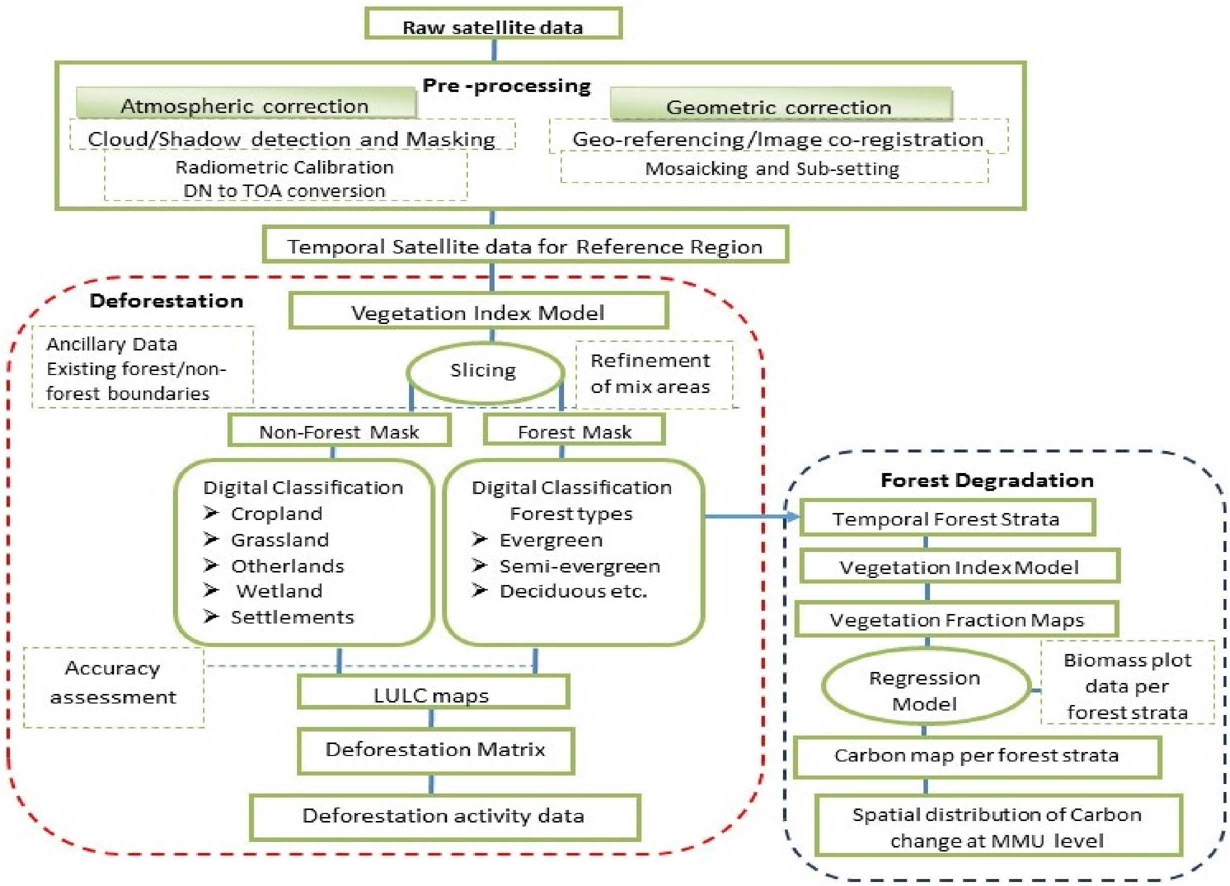
The vegetation fraction map/density map must be divided as per the forest types present in the landscape to form the forest strata. The project proponent may use strata based on forest type or density or a combination of both. In order to assess forest degradation, a transition matrix must be developed between the changes in area among the fractional cover/density classes in a particular forest type.

The basis of applicability of forest degradation mapping is the integration of temporal vegetative fraction or canopy density with field carbon data (emission factor), which may be done separately for each forest stratum. Nationally accepted sampling strategies for forest inventory may be used in this process. In the absence of such sampling designs, the project proponent may use a peer reviewed sampling technique. In such scenarios, in order to decide the number of sample plots per strata, refer to the equations in CDM methodological tool *Calculation of the number of sample plots for measurements within A/R CDM project activities*.

An example of a detailed workflow is shown in Figure 7 below.

[7] Decadal forest cover loss analysis over Indian forests using MODIS 250m imagery, Conference: ISPRS Technical Commission VIII Symposium, 09 – 12 December 2014, Hyderabad, India, At Hyderabad, India, Volume: The International Archives of the Photogrammetry, Remote Sensing and Spatial Information Sciences, Volume XL-8, 2014

Figure 7: Workflow of Remote Sensing Approach for Baseline Emissions Estimation



8.1.5.2 Analyze LULC Change

Based on the remote sensing analysis, the historical LULC in the reference region must be analyzed for assessing the baseline scenario and quantifying the rates of deforestation and forest degradation. Analysis of the RS data provides the historical changes and current status of LULC dynamics within the reference region.

8.1.5.3 Accuracy Assessment of LULC Maps

Reporting accuracy and verification of results are essential components of a monitoring system. Accuracy may be quantified following recommendations of Section 5 of IPCC *Good Practice Guidance 2003, Chapter 3A.2.4 of IPPC 2006 Guidelines for AFOLU*, and the most recent version of the *GOFC-GOLD Sourcebook* on monitoring and reporting anthropogenic greenhouse gas emissions and removals caused by deforestation, gains and losses of carbon stocks in forests remaining forests, and forestation.

Complete cloud-free satellite maps must be used where available. However, multiple images of the same year may be used so that the cumulative impact of cloud cover for all time points is ≤ 10% of the RR (e.g., in t1, t2 and t3, percent cloud covers are x, y & z, where x+y+z ≤10). Cloud cover and cloud shadow areas must be removed from the baseline calculation. The project proponent may also refer to VCS tool *VT0006 Tool for Calculating LULC Transitions and Deforestation Rates Using Incomplete Remote Sensing Images* for guidance. As an alternative option, project proponents may also use a hybrid approach of Synthetic Aperture Radar (SAR) techniques in areas where heavy cloud cover exists most of the year. In that scenario, combined carbon stock maps must be prepared from both optical and SAR datasets and merged to create a seamless dataset of any year.

With reference to the above, accuracy must be estimated on a class-by-class (LULC map) basis and, where applicable, category-by-category (LULC-change map) basis, respectively. At least 25 validation points for each strata of the area being analyzed must be selected and an error matrix must be presented. The diagonal must show the proportion of correct classification and the off-diagonal cells must show the relative proportion of misclassification of each class or category into the other class or, respectively, categories. Based on the error matrix (or confusion matrix), a number of accuracy indices may be derived.

The minimum accuracy for the forest to non-forest map must be 85 percent. The minimum classification accuracy of each class or category in the Land-Use and Land-Cover Map and Land-Use and Land-Cover Change Map, respectively, must be 80 percent. Where the classification of a class or category is lower than 80 percent, the project proponent should consider merging the class/category with other classes/categories, or excluding the forest-classes from the Forest Cover Benchmark Map that are causing the greatest confusion with non-forest classes according to the error matrix (e.g., initial secondary succession and heavily degraded forest may be difficult to distinguish from certain types of grassland or cropland, such as agro-forestry and silvopastoral systems not meeting the definition of forest).

Both commission errors (false detection of a class/category, such as deforestation) and omission errors (non-detection of actual class/category, such as deforestation) must be estimated and reported.

In order to assess the accuracy of forest degradation mapping, the vegetation fraction/forest cover density model outputs must be validated for each density classes within the forest type with ground observation. The correlation of mapped and ground observed density must be analyzed based on linear regression, or any other statistically appropriate technique with proper justification and a minimum correlation coefficient of 0.7.

For past data validation, high-res and in-situ maps must be used. In the absence of high-res and in-situ maps, accuracy may be assessed by surveys such as Focused Group Discussions (FGDs), expert interviews, focal point interviews and published scientific literatures.

8.1.6 Assess Forest Transition and Forest Scarcity

The “forest transition” concept was introduced by Mather in 1992 (Mather A. , 1992), and is used to demonstrate the manner in which forest cover first declines, reaches a minimum, and then the forest cover again rises and eventually stabilizes. It was demonstrated that with economic development, industrialization, and other DoFC, the forest cover changes in predictable ways.

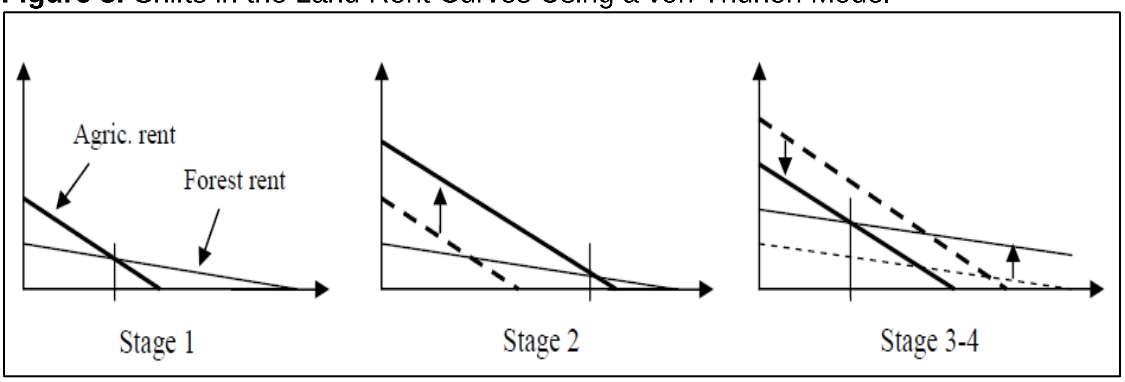
(Mather A. a., 1998). The theory also demonstrates that areas with vast forest cover which are initially characterized by rapid deforestation rates eventually stabilize the forest area after some time. Hence, it would be incorrect to assume that there will be linear decrease in forest until the forest land changes to other land use class. Forest transition was also demonstrated on the basis of Von Thünen framework (Angelsen, 2007).

The stages of forest transition are as follows:

1) Undisturbed forest: inaccessible forest with poor infrastructure and access to market.
2) Deforestation starts: DoFC starts acting on the forest and deforestation begins at a high level leading to forest scarcity. As deforestation begins, a reinforcing loop enlarges the DoFC due to expanded infrastructure and access. Further, the socio-economic and political pressure leads to converting reinforcing into stabilization loops (i.e., leading to a reduction in the rate of deforestation).
3) Forest scarcity: leads to mosaic deforestation/degradation as well.
4) Stabilizing loops dominate leading to recovery of the forest cover (natural or assisted). This was demonstrated by Rudel et al, 2005[8], that the stabilizing loops are mainly due to forest scarcity (i.e., increase in forest demand) and an economic development path (i.e., increased opportunity outside the triggering forces of forest change, like agriculture, and NTFP marketing). In 2013, Angelsen and Rudel, found that forest scarcity and other drivers like scarcity of ecosystem services, diminishing agriculture rent, economic development and policy/regulations changes may provide a strong stimulus for forest conservation and better forest management.

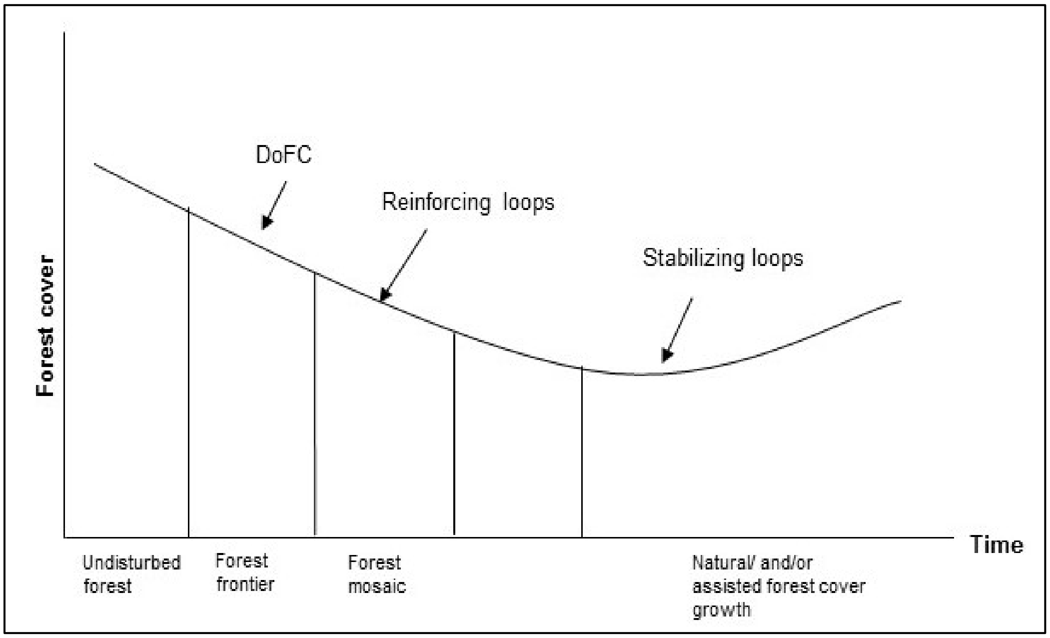
An example of the stages of forest transition is adapted from the Angelsen 2007 paper, as seen in Figures 8 and 9 below.

Figure 8: Shifts in the Land Rent Curves Using a von Thünen Model[27]



[8] Rudel, Thomas K., Oliver T. Coomes, Emilio Moran, Frederic Achard, Arild Angelsen, Jianchu Xu, and EricLambin. 2005. Forest transitions: towards a global understanding of land use change. Global Environmental Change 15:23-31. http://www.greenbiz.com/sites/default/files/document/CustomO16C45F64217.pdf

Figure 9: Main Stages of Forest Loss[9]



The forest transition theory makes two claims:

1) Where there is a significant area of forest there will (eventually) be a significant area of deforestation, while there will be limited deforestation in areas with little forest.
2) Forest cover eventually will be fully or partially restored and stabilized either through natural re-growth or plantations or both.

Since anthropogenic *forest transition* is not a natural process, and is influenced by various socio-economic scenarios, countries may be able to bridge the forest transition and save it from reaching very low levels before it stabilizes.

Detailed assessment of forest transition on the basis of forest scarcity must be made. Published and peer reviewed prediction and assessment methods must be adapted to calibrate and calculate forest scarcity (e.g., *Modeling the Forest Transition: Forest Scarcity and Ecosystem Service Hypotheses*, Akiko Satake and Thomas K. Rudel, 2007).

The average annual transition of land from one forest stratum to another must be estimated for the historical reference period. The historical reference period may be further broken down into two or more time periods. Conditions on selecting the time points in the historical reference period are given Section 223.

The transition must be estimated by mapping the change from one stratum to another, including both forest and non-forest strata, during one of the time periods and calculating the rate of annual transition in each of the stratum as follows:

[9] Adapted from Arlid Angelsen, 2007. Forest Cover Change in Space and Time: Combining the von Thünen and Forest Transition Theories, CIFOR and UMB, World Bank Policy Research Working Paper 4117

$$LT(1 \rightarrow 2)_{y2-y1} = (LC1_{y1} \rightarrow LC2_{Y2})/(y2 - y1)$$ Equation **1**

Where:

$LT(1\text{-}2)_{y2\text{-}y1}$	= Annual average land transition from stratum 1 to stratum 2 from time-point y_1 to time-point y_2 (ha)
$LC1_{y1} \rightarrow LC2_{Y2}$	= Total land classified as stratum LC1 (ha) in time point y1 which has undergone transition to land classified as stratum LC2 (ha) in time point y2 (ha)
Y_1	= Year of first time-point in the land transition analysis
Y_2	= Year of second time-point in the land transition analysis

From this value, the average annual rate of shift from one stratum to another (expressed as a percentage) is also estimated as follows:

$$LT(1 \rightarrow 2)_{y2-y1,rate} = (LT(1 \rightarrow 2)_{y2-y1}/LC1_{Y1}) * 100$$ Equation 2

Where:

$LT(1\text{-}2)_{y2\text{-}y1,\ rate}$	= rate of annual average land transition from stratum 1 to stratum 2 from time-point y_1 to time-point y_2 (%)
$LT(1\text{-}2)_{y2\text{-}y1}$	= Annual average land transition from stratum 1 to stratum 2 from time-point y_1 to time-point y_2 (ha)
$LC1_{y1}$	= Total land classified as stratum LC1 (ha) in time point y1 (ha)

This estimate must be conducted for each of the historical time-points selected for analysis of land transitions. Where more than four historical time-points are considered, the rate of transition from one stratum to another may be developed using regression equations. In the case of three time-points, the average rate of transition may be considered to estimate the overall rate of transition of forest from one stratum to another over the historical reference period. For estimation of baseline emissions, the rate of change of one stratum to another for the entire historical reference period must be estimated.

The same rate of change in the reference region must be applied to the project area. Models of forest scarcity must be applied appropriately to ensure that the rate of change of land from one stratum to another does not result in its complete loss before the end of the project crediting period. If it does, then emissions must be accounted for by:

1) Not accounting for emissions from those strata from that time point at which they will undergo complete transition to other strata; or
2) Applying a discounting factor to evenly distribute the estimated emissions in the entire project crediting period. The discounting factor may be calculated as the ratio of the time taken for the stratum to completely undergo the change to the total crediting period.

The discount factor referenced in (2) above must be calculated as follows:

$$N_{LT} = yLT(j), trans/\ y\ crediting\ period$$ Equation 3

Where:

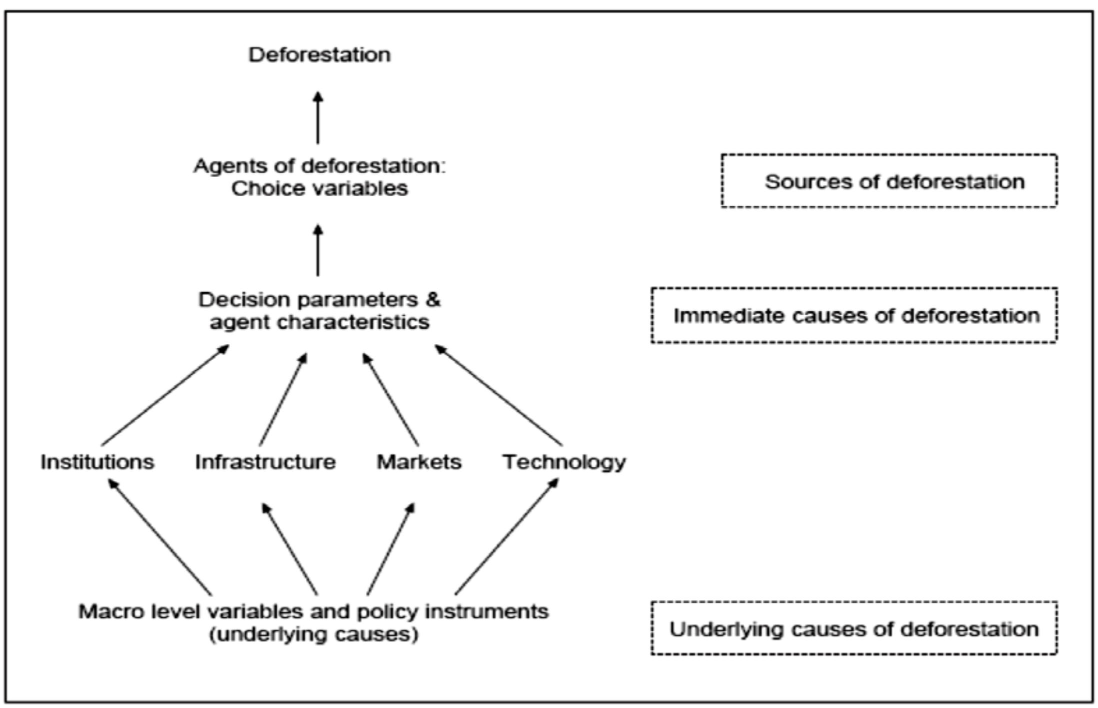
N_{LT}	= land transition discounting factor due to scarcity of land
$y_{LT(i),trans}$	= time taken for the stratum(i) to completely undergo transition to other strata (years)
$y_{crediting\ period}$	= project crediting period (years)

8.1.7 Analyzing Drivers of Forest Change (DoFC)

The project proponent must analyze the DoFC by considering and addressing the points given below:

1) National level driver analysis must be used for the project where available.
2) Where national level driver analysis is not available, or where it can be justified by the project proponent that national level driver analysis is not appropriate for use by the project, the project proponent must conduct a detailed analysis of drivers of forest change. This may be based on internationally accepted norms, such as the five factors proposed by David Kaimowitz and Arild Angelsen (1998) as described in Figure 10 below:

Figure 10: A Framework of Different Types of Variables Affecting Deforestation[10]



[10] Adapted from Kaimowitz, 1998

The project proponent must use the five simplified factors as detailed by David Kaimowitz and Arild Angelsen (1998) on which the analysis of DoFC depends, as given below:

1) **Magnitude and location of deforestation:** Assessed through RS analysis and field surveys.
2) **Agents of deforestation (sources of deforestation):** Analyze the major agents acting and involved in the region causing the forest change (e.g. individual, community, companies).
3) **Choice drivers/variables (sources of DoFC):** Determine the drivers and variables that result in the forest change activities undertaken by the agents (e.g., a community will clear land for agriculture activity or will encroach into the forest for NTFP extraction, whereby a community is an agent, agriculture activity and NTFP extraction are variable). Examples of this include, but are not limited to, the following:
    - Land allocation
    - Labour allocation and migration
    - Capital allocation
    - Consumption
    - Other technological and management decisions
4) **Agent decision parameters (immediate cause of deforestation):** These variables directly influence agents' decisions with respect to the choice variables, but are external to individual agents. This parameter decides the amount of forest change. Examples of this include, but are not limited to, the following:
    - Labor costs,
    - Other factor (input) prices,
    - Accessibility,
    - Available technology and information,
    - Risk,
    - Property regimes,
    - Government restrictions
    - Other constraints on factor use,
    - Environmental factors (physical).
5) **Macro-level variables and policy instruments or the underlying cause:** The impact of these variables are not direct on the agents. However, they impact forest change by affecting and influencing the agents' decision parameters. Examples of this include, but are not limited to, the following:

- Population growth/density of a country,
- Forest dependency ratio,
- Government policies,
- Tariffs,
- Tax rate,
- International exchange rate.

The estimation of the area affected and magnitude of DoFC is done through RS analysis. However, the estimation of land specific values for a given parameter and variables relies heavily on field sampling, which is frequently done through national forest inventories (Tier 2) and project measurement (Tier 3) data. REDD is not only associated with carbon and forest canopy, but also involves social, environmental and economic dimensions.

Based on the historical evidence collected from remote sensing analysis and socio-economic mapping, the project proponent must analyze the relationship between the main agent groups, key drivers, and underlying causes, and explain the sequence of events that typically leads to deforestation and degradation.

Table 5: Approach for Assessing and Evaluating the Socioeconomic Impacts of REDD

Methods of socioeconomic analysis		Stakeholder consultation	Prediction based on stakeholders' views	Use existing data	Collect own data
Primary data	Participatory Rural Appraisal	✓	✓	X	✓
	Household Survey	✓	✓	✓	✓
	Key informant interviews	✓	X	X	✓
	Focus group discussions	✓	X	X	✓
Secondary data	Population census, published scientific literature	X	X	✓	X

The design of survey tools must be made in a way that makes the understanding of natural resource management easier, leading to development and effective implementation of intervention activities. It must also provide information between the decision making system of the government, and the trends and priorities of the local communities. Similarly, information on community based institutions and their role in sustainable conservation of natural resources must be obtained which may be useful in understanding land tenure and rights. Socioeconomic assessments are therefore an efficient and cost effective tool for understanding the social, economic, cultural and political aspects of all the involved stakeholders. However, certain tools are more effective in mapping certain DoFC, which is detailed in the Table 7 below. The same must be demonstrated at the time of validation.

Table 6: Effectiveness of Selected Socio-Economic Tool in Evaluating the DoFC

Socio-economic tool	Drivers							
	Unsustainable extraction of Fuel-wood	Unsustainable extraction of NTFP	Uncontrolled grazing and fodder collection	Expansion of subsistence agriculture by conversion of forestland	Unplanned timber harvesting	Anthropogenic Forest fire	Encroachment	Unplanned mining and quarrying
Participatory Rural Appraisal (semi-structured focus group discussions)	Yes	Yes	Yes	Yes	NA	Yes	Yes	Yes
Household Survey	Yes	Yes	Yes	Yes	Yes	NA	Yes	NA
Key informant interviews	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Focus group discussions	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Government census and records.	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes

This methodology allows different tools to collect socio-economic data, *inter alia*, including, but not limited to:

1) Detailed survey questionnaire
2) Checklist
3) Interviews and discussion notes
4) Interviews and discussion with audio and video records
5) Observation notes
6) Records of earlier surveys and studies

The frequency of conducting surveys must be at least once before every baseline update.

A statistically sound sampling design must be applied or any national/sub-national methodology or standard that is applied for government surveys also may be used. For example, 10 percent with 90 percent confidence level may be considered. Adequate geographical representation also must be appropriately considered in the sampling design.

8.1.7.1 Quantification of Carbon Stock Changes

Data regarding extraction from forests must be derived from the surveys on DoFC mentioned above. These changes in carbon stock and associated emission factors must be computed, and must also be used for back-calculations in assessing the robustness of changes in carbon stock resulting from spatial analysis.

8.1.8 Baseline Emissions from REDD Activities

Deforestation is the change of forest land into other land uses. The change in carbon stock must be derived directly in two GIS approaches: fractional downscaling, and using microwave applications such as SAR analysis and associated algorithms. Ground validation involves estimation of the carbon stock of each of the identified strata.

Stratification must be based on national guidelines. In the absence of national guidelines, forest must be classified into different forest types as per established international ecological norms. The carbon stock of each type of forest must be estimated from ground ecological data collected from each stratum. Carbon stock in each of the identified carbon pools must be estimated in each stratum. Where a national standard exists on forest inventory, the same may be followed. In the absence of such guidance, the requirements below must be followed.

Forest lands in the reference region must be divided into appropriate strata, based on forest types, and other sub-strata as applicable (such as aspect and slope). The carbon pools must then be identified and listed. The carbon pools considered in this methodology are detailed in Section 3 above. AGB measurement involves quantification of the carbon content of trees.

A statistically significant sampling methodology must be applied based on the IPCC GPGLULUCF or CDM tool on sampling. The size of the sample plots must be at least 0.25 ha for quantification of AGB. A smaller plot may be chosen based on regional or national guidance or other accepted international norms. A detailed inventory of all trees must be prepared with data and parameters collected which includes DBH and the height of the trees. The total living biomass carbon content of the strata is computed on a per hectare basis for each stratum.

Where the project proponent is including the SOC (i.e., the case where the baseline scenario is annual crop), the most recent version of the CDM methodological tool *Tool for estimation of change in soil organic carbon stocks due to the implementation of A/R CDM project activities* must be applied.

Carbon content per hectare of a stratum must be estimated from the carbon estimations from the sample plots. Carbon stock in each of the pools must be estimated separately. Regional and national volume equations and allometric equations may be used for estimating AGB. Biomass Expansion Factors (BEF) may be sourced from IPCC GPG LULUCF. Wood density specific to the species of trees may be sourced from regional/national specific sources. Standard root to shoot ratios may be used for estimating BGB. Nationally applicable methodologies or techniques from peer reviewed publications will be applied for estimation of SOC, carbon content in deadwood, litter and other carbon pools.

$$\mathrm{C} - St_i = \Sigma(\mathrm{C})_{c-pool,i,SP} * 1/\mathrm{SP}$$ Equation 4

Where:

$C\text{-}St_i$	= Carbon stock per hectare of stratum i (tC/ha)
$(C)_{C\text{-}pool,I,SP}$	= Carbon stock in each of the carbon pool in the sample plot in stratum i (tC/sample plot)
SP	= Area of sample plot (ha)

Change in carbon stock due to degradation must be based on fractional downscaling or other such algorithm based analysis using SAR or LIDAR technology. In the absence of such technology, each forest type must be further divided based on the canopy cover. A minimum of 4 strata based on canopy cover must be established based on national approaches. In the absence of any national approach, or where it is better suited for the analysis, the forest canopy must be divided in such a way that each canopy density class is separated by at least 10 percentage points. Carbon stock of each of the stratum must be measured as explained in the section on deforestation. Emission factor matrices must be developed for each of the forest type, where the changes in carbon stock must be detailed where there is a change in the canopy classes.

This quantification must give details of carbon change in forests due to degradation in forest lands. From this data, an emission factor matrix on deforestation is developed which must give the emission factors for change from forest land to non-forest land. A second emission factor matrix must be developed based on changes from one forest type to another. These two matrices may be integrated into the same matrix depending on the techniques applied.

$$\mathrm{EF}\ (LT)(1 \rightarrow 2)_{y2-y1} \ = \ (CSt1_{y1} \rightarrow CSt1_{y2})$$ Equation **5**

Where:

EF(LT)(1→2)	= Change in carbon stock associated to transition from stratum 1 to stratum 2 (tC/ha)
CSt1	= Carbon stock in stratum 1 (tC/ha)
CSt2	= Carbon stock in stratum 2 (tC/ha)

From the net change in the carbon stock in the baseline scenario, the trend in change in the carbon stock is developed. This may be a linear regression projection or an average of each time point in case there are only three time points in the analysis. The total loss of carbon stock from the project area in the baseline scenario is computed as:

$$\mathrm{BSL}_{C,si} \ = \ \mathrm{EF(LT)(1{\rightarrow}2)} * \left((LT(1-2)_{y2-y1,rate}\right) * S_{REDD,i}$$ Equation 6

Where:

$BSL_{c,si}$	= Change in carbon stocks due to land transitions in the baseline in the REDD project area (tC/ha)
EF(LT)(1→2)	= Change in carbon stock associated to transition from stratum 1 to stratum 2 (tC/ha)
LT(1-2)y2-y1, rate	= rate of annual average land transition from stratum 1 to stratum 2 from time-point y1 to time-point y2 (%)
$S_{REDD,i}$	= Area in stratum i within the REDD project area (ha)

The total baseline emissions is estimated using the below equation.

$$\mathrm{BE}_{yREDD} \ = \sum(BSL_{C.si}) * 44/12$$ Equation 7

Where:

BE_{yREDD}	= Baseline emissions from REDD (tCO_2)
$BSL_{C,si}$	= Net change in carbon stocks due to land transitions in the baseline in the REDD project area (tC)

8.1.8.1 Additional Baseline Emission Sources

Detailed quantification of changes in carbon stock is already provided in previous sections where a full field analysis is conducted. This gives the net change in carbon in the landscape, and must also help in the landscape approaches of measuring changes in carbon stock.

However, the methodology also provides for a safeguard by allowing the project proponent to analyze the changes in land use and land cover in the reference region based on activity data. Based on the regression equations or the average rate of change from one LULC class to another, the rate of change from each LULC class to another is computed. The rate of change from each of the strata to other strata is also computed. Statistically insignificant changes may be ignored. From the emission factor matrices developed, and the LULC pattern within the project area, the baseline emissions in the project area may be computed.

In cases where ARR is involved, the baseline must include existing trees within the project area. Conservatively, the change in carbon stock within the baseline trees may be considered as zero, after application of appropriate tools regarding computing change in carbon stock which are approved under VCS or CDM. However, only living biomass carbon stock is to be considered in ARR components.

The project proponent must clearly record the contribution of each of the drivers to forest change and the effectiveness of the implementation of the intervention activity. This must be reflected in the ex-ante quantification. Ex-post emission reduction estimations are not based on the effectiveness values. The effectiveness of any driver intervention activity depends on local conditions and on probability of adoption of intervention activities. Contribution of each driver in causing emissions may be based on different instruments, such as surveys (FGDs and PRAs) published scientific literature, documented expert opinion, and pilot studies. Effectiveness in implementation must be measured on a scale of 0-1, where 0 is not at all effective and 1 is 100 percent effective. Table 8 provides an example of this below.

Table 7: Contribution of Each Drivers of Deforestation and Forest Degradation

Drivers	Contribution	Effectiveness of the intervention activity	Contribution factor (Con-F) to reductions in emissions
Driver 1	X%	0.a	$Con\text{-}F_1$ = X% * 0.a
Driver 2	Y%	0.b	$Con\text{-}F_2$ = Y% * 0.b
Driver 3	Z%	0.c	$Con\text{-}F_3$ = Z% * 0.c
…	…	…	

Once this is calculated, there is no need to calculate emissions due to each of the driver, except for back calculations and redundancy checks during monitoring and verification. The calculations for major drivers only for the redundancy checks are given below.

Carbon losses due to each of the drivers must be analyzed from the scientific studies in the reference region. This is used to assess and calculate the emission reductions for back-calculations and redundancy checks. The carbon losses due to each of the active and major drivers must be computed. Deforestation and degradation caused due to each of the drivers must be given a weight based on the scientific estimate and surveys, which must be the same as that provided in the Table 8 above. The intervention activities to counter each driver must be detailed. Efficiency of each driver also must be considered. This analysis is not mandated for ex-post estimation as ex-post estimations must be based on the actual stock, irrespective of the drivers and success of the intervention activities planned, but must help in redundancy checks. The major drivers are presented below for the redundancy checks.

Additional baseline emission sources shall be calculated as follows:

$$\mathrm{BE}_{yADD} = L_{fuelwood} + C_{fire} + C_{felling} + C_{ill} \qquad \text{Equation 8}$$

Where:

BE_{yADD}	= Total additional baseline emissions (tCO_2)
$L_{fuelwood}$	= Annual carbon loss due to fuelwood gathering, tonnes C. yr^{-1} per species
C_{fire}	= Annual carbon loss due to forest fire, tonnes C. yr^{-1}
$C_{felling}$	= Annual carbon loss due to timber harvesting, tonnes C. yr^{-1}
C_{ill}	= annual carbon loss due to illegal activities C. yr^{-1}

Fuelwood

The total amount of fuelwood consumed must be assessed from surveys. At least three sample weighs from each of stratum must be collected to validate the amount of fuelwood collected. Total fuelwood collected from forests and from other sources must be recorded separately. The values considered must be “air dry” biomass and moisture account for a maximum of 12 percent of the weight (FAO, 2003)[11] is deducted. A survey based assessment is sufficient to estimate consumption at larger spatial scales when logistic limitations make impossible following stocks of hundreds of households (Jones et. al., 2008).[12] Carbon loss from fuelwood assessed from surveys is calculated as follows:

$$L_{fuelwood} = FG_i \times D_i \times BEF \times CF \qquad \text{Equation 9}$$

Where:

$L_{fuelwood}$	= annual carbon loss due to fuelwood gathering, tonnes C. yr^{-1} per species
FG_i	= annual volume of fuelwood species i gathered, m^3 yr^{-1}
D_i	= basic wood density of fuelwood species, tonnes d.m. m^{-3}

[11] A Guide for Woodfuel Surveys, 2003. Sustainable Forest Management Programme. FAO, Rome.
[12] http://onlinelibrary.wiley.com/doi/10.1111/j.1365-2664.2008.01487.x/full

BEF = biomass expansion factor for converting volumes of extracted wood to total aboveground biomass (including bark), dimensionless;

CF = carbon fraction of dry matter (default = 0.5), tonnes C (tonne d.m.$^{-1}$)

Where the weight of the fuelwood is directly calculated, the above equation must be ignored, and the weight must be directly extrapolated to calculate the total carbon loss due to fuelwood collection. Carbon loss from fuelwood is directly calculated as follows:

$$L_{fuelwood} = W_{fw} * CF \quad \text{Equation 10}$$

Where:

$L_{fuelwood}$ = annual carbon loss due to fuelwood gathering, tonnes C. yr^{-1}

W_{fw} = annual weight of fuelwood gathering, t yr^{-1}

CF = carbon fraction of dry matter (default = 0.5), tonnes C (tonne d.m.$^{-1}$)

Anthropogenic Forest Fire

Only forest fires that originate due to human induced activities may be considered. All forest fires must be mapped. The cause of forest fires must be ascertained as much as possible. If this is not possible, a perception-based demarcation of cause of forest fires may be done based on FGDs. The following two categories are mandatory:

1) Human induced fires.
2) Fires which are not started by human activity.

Only human induced fires are considered in this methodology. The methodology uses GOFC-GOLD Sourcebook, 2013 equation no. 2.6.2, which is an indirect method of estimating anthropogenic emissions from forest fire of IPCC guidelines. Carbon loss from fires is calculated as follows:

$$C_{fire} = Ax_{fire} \times Fl \times Be \times EF \times 10^{-3} \quad \text{Equation 11}$$

Where:

C_{fire} = annual carbon loss due to forest fire, tonnes C. yr^{-1}

Ax_{fire} = Area lost due to forest fire, ha Yr^{-1}

Fl = Fuel loading per unit area, g m-^{2}

Be = Burning efficiency, dimensionless

EF = Emission factor g kg^{-1}

To quantify emissions from forest fires, the area subject to fire must be characterized and stratified into forest types or ecological zones and further sub-divided in terms of fire characteristics (e.g., crown fires which are primarily uncontrolled, intense fires leading to large losses of forest covers, surface fires burning litter and undergrowth).

The quantification method uses a three-tiered approach. However, the project proponent must apply a Tier 3 or Tier 2 approach (i.e., in the absence of region specific data, country level data may be used). In the absence of any country level data, Tier 1 data may be applied.

To map forest fire, moderate resolution satellite data may be used and must have a spatial resolution not coarser than 100 m pixel size. Sub-hectare mapping of forest fire is not allowed in this methodology. Where the forest fire scars in the mapping are less than one hectare, such must not be considered. Monitoring and mapping the understory fire may need analysis based on SAR and appropriate ground validation. In the absence of country specific directions and procedures on SAR analysis, international sources may be used. GHGs other than CO_2 which may be emitted due to forest fires must also be accounted for if they are found to be significant (more than 5 percent of total emissions due to forest fires). Nationally accepted proxies or IPCC default values may also be used in the absence of any local data.

Unplanned Timber Harvesting

Wood that is harvested directly, without being sold, may not be included in the official statistics and must be estimated by survey. Hence, the project proponent must carefully consider these issues. Also, this activity is essentially linked with the socio-economic and geographical conditions of a particular area, and therefore may only be estimated through a Tier 3 approach. Similarly, the FAO approach used for fuelwood estimation may be applied to quantify timber harvesting by local communities. This estimation information must be incorporated into carbon emission accounting algorithms. Carbon loss from timber harvest is calculated as follows:

$$C_{felling} = HT_i \times D_i \times BEF \times CF \quad \text{Equation 12}$$

Where:

$C_{felling}$	= annual carbon loss due to timber harvesting, tonnes C. yr^{-1}
HT_i	= annual volume of harvested timber, species i, m^3 yr^{-1}
D_i	= basic wood density of species i, tonnes d.m. m^{-3};
BEF	= biomass expansion factor for converting volumes of extracted wood to total aboveground biomass (including bark), dimensionless;
CF	= carbon fraction of dry matter (default = 0.5), tonnes C (tonne d.m.)$^{-1}$

Illegal Mining and Quarrying, Encroachment and Expansion of Subsistence Agriculture by Conversion of Forest Lands

These drivers causing change in forest carbon must be illegal and unplanned, and therefore not accounted for in the national inventories. A Tier 3 approach may be used to assess the changes in the forest carbon stock due to illegal mining and quarrying, encroachment and expansion of subsistence agriculture. Analysis of satellite imagery (LULC change matrix) from the past is an effective way to estimate the carbon stock loss due to these activities. Further, to quantify the carbon emissions due to forest loss as a result of these activities, IPCC GPG LULUCF guideline equation no 3.2.9 must be followed. These losses are calculated as follows:

$$C_{ill} = A_{ill} \times B_w \times (1 - f_{biol}) \times CF \qquad \text{Equation 13}$$

Where:

C_{ill}	= annual carbon loss due to illegal activities C. yr^{-1}
A_{ill}	= forest area affected by illegal activities, ha yr^{-1}
B_w	= average biomass stock of forest areas, tonnes d.m. ha^{-1} (Tables 3A.1.2, 3A.1.3, and 3A.1.4 of IPCC GPG LULUCF)
f_{biol}	= fraction of biomass left to decay in forest (transferred to dead organic matter) (Table 3A.1.11 of IPCC GPG LULUCF)
CF	= carbon fraction of dry matter (default = 0.5), tonnes C (tonne d.m. $^{-1}$)

Grazing and Fodder

In order to quantify carbon losses due to grazing and fodder, studies on biomass consumed during grazing or extracted as fodder from forests must be used. In the absence of such studies, pilot studies may be carried out where the amount of biomass lost due to grazing is recorded. Since quantifying loss of biomass due to grazing and fodder collection also must consider different cultural practices, region specific or peer reviewed tools or methods may be applied to quantify this. The generic approach explained below may also be applied. In case the impact is found to be less than 5 percent, carbon losses due to grazing and fodder may be considered *de minimis*.

The total number of livestock grazing in the area must be estimated. Emissions from grazing are to be accounted for only if the total livestock grazing in the project area is more than the carrying capacity as estimated by the government or reported in peer-reviewed literature for the project area, or per unit of a similar landscape (same bio-geological zone), or else nationally recognized data may be used. Dry matter intake of cattle must be calculated based on the body weight of the livestock and estimated dietary net energy concentration of diet as explained in *IPCC Guidelines for National Greenhouse Gas Inventories 2006*. Since some supplementary feed might be given by herders, this must be considered in the quantification method, and must be established from surveys, government reports, or peer reviewed literature. From actual dry matter intake per cattle unit, dry matter intake by all the livestock that graze in the forest land must be calculated.

Available forage of the forest land may be estimated with reference to the past records of stocking rates of the grazing land reported by government agencies or research institutes. If the historical trend of the quality of the grazing land is steady or shows a decline, conservatively, the same stocking rate may be considered or must otherwise be revised. In the absence of any historical rates, available forage of similarly managed forests/grazing lands may be applied or else national data may be applied. From actual dry matter intake per animal and the available stocking rate, carrying capacity may be calculated.

Total carbon content in the intake must then be calculated from the difference of available forage and the dry matter intake of all the livestock that graze in the forest. Carbon fraction of the forage must then be either estimated in laboratory tests or is referred to from peer-reviewed literature including government reports. From carbon emissions due to grazing, carbon added to the forest soil in the form of excreta is discounted to avoid any double counting in instances where SOC is accounted as a carbon pool in the project. The discounting factor may be tier-2 data also based on carbon balance studies in pasture lands. This discount factor is to be conservatively applied.

Non-Timber Forest Produce (NTFP)

Where it is found that extraction of NTFP leads to unsustainable losses in biomass, the resulting emissions must be accounted for. This may be done by listing every NTFP that contributes to at least 5 percent of total extracted NTFPs in the reference region by quantity. This may be established through surveys, expert opinion, key informant interviews and secondary literature studies where the use of the NTFPs and the plant parts are recorded. The damage due to extraction of each of the NTFP must be assessed based on expert opinion, direct observations and recording, and/or surveys in such a way that the extraction practices are taken into account. Where government reports or information from peer reviewed literature is available on the carrying capacity of a particular NTFP, the same may be used. In the absence this, expert opinion on the carrying capacity must be established.

8.1.9 Baseline Emission Removals from ARR Activities

Estimation of baseline emission removals from ARR activities must refer to methodology *AR-AMS0007*, the equations for which are presented below.

The baseline net GHG removals by sinks must be calculated as follows:

$$BE_{ARR} = \Delta C_{TREE\_BSL,t} + \Delta C_{SHRUB\_BSL,t} + \Delta C_{DW\_BSL,t} + \Delta C_{LI\_BSL,t} \qquad \text{Equation 14}$$

Where:

$\Delta C_{TREE\_BSL,t}$ = Change in carbon stock in baseline tree biomass within the project boundary in year *t*, as estimated in the tool *Estimation of carbon stocks and change in carbon stocks of trees and shrubs in A/R CDM project activities*; tCO_2e

$\Delta C_{SHRUB\_BSL,t}$ = Change in carbon stock in baseline shrub biomass within the project boundary, in year *t*, as estimated in the tool *Estimation of carbon stocks and change in carbon stocks of trees and shrubs in A/R CDM project activities*; tCO_2e

$\Delta C_{DW\_BSL,t}$ = Change in carbon stock in baseline dead-wood biomass within the project boundary, in year *t*, as estimated in the tool *Estimation of carbon stocks and change in carbon stocks in dead wood and litter in A/R CDM project activities*; tCO_2e

$\Delta C_{LI\_BSL,t}$	=	Change in carbon stock in baseline litter biomass within the project boundary, in year *t*, as estimated in the tool *Estimation of carbon stocks and change in carbon stocks in dead wood and litter in A/R CDM project activities;* tCO_2e
BE_{ARR}	=	Total baseline emission removals by sinks, tCO_2e

8.2 Project Emissions (PE)

Project emissions are the emissions which occur inside the project boundary as a result of the project activities.

8.2.1 Project Emissions from REDD Activities

Project emission from REDD activities are provided in Table 9.

Table 8: Sources of Project Emissions

Parameters	Description
Fossil fuel combustion (PE_{ff})	Combustion of all types of fossil fuels associated with the project must be calculated. Activities such as forest patrolling, biomass ground inventory, fire prevention activities, installation of fences, boundary poles, Assisted Natural Regeneration (ANR) activities, introducing and providing intervention activities, eco-tourism (if allowed), NTFP market channel and other activities (as livelihood options) (distance travelled by vehicle type, type of fossil fuel used, type of machine used, quantity of fossil fuel used, inside and outside of the project boundary as a part of the project activity/ies). Reference tool: CDM *Tool to calculate project or leakage CO_2 emissions from fossil fuel combustion*
Woody biomass removal for fire prevention activities (PE_{wbf})	Loss of carbon must be accounted for if losses of woody biomass takes place due to activities such as installation of fire breaks, clearing of shrubs, dry and dead wood, invasive species, small trees that may act as fuel for fires, thinning of forests to prevent wildfires, or burning woody biomass. Reference tool: CDM tool for *Estimation of non-CO_2 GHG emissions resulting from burning of biomass attributable to an A/R CDM project activity.*
Woody biomass removal during assisted natural regeneration (ANR) activities (PE_{wbanr})	Loss of carbon must be accounted for if removal of woody biomass such as short trees and shrubs, dead wood, invasive species takes place due to project activities, to allow natural regeneration. Reference tool: CDM tool *Estimation of non-CO2 GHG emissions resulting from burning of biomass attributable to an A/R CDM project activity* must be applied and the resulting emissions must be accounted.

Increased use of fertilizer (PE_f)	Application of fertilizer causing significant N_2O emission from the project activity must be accounted for. Reference tool: CDM tool for *Estimation of direct nitrous oxide emission from nitrogen fertilization to calculate emission.*
Biomass burning/ Fire from natural disturbance/ Forest fire used for harvesting/ site preparation (PE_{bb})	Emissions from biomass burning in the project scenario, whether due to anthropogenic or natural disturbances or as a part of the project activities, must be accounted for. Reference tool: CDM tool for *Estimation of non-CO_2 GHG emissions resulting from burning of biomass attributable to an A/R CDM project activity* to calculate emission.
Unplanned timber harvesting (PE_{uthy})	Where the socio-economic survey finds that there is no unplanned extraction of timber from the project area, then the emissions from unplanned timber harvesting may be assumed to be zero. Reference tool: PE due to unplanned timber harvesting must be estimated using equation no. 11, Section 8.1.8.1, which is based on IPCC GPG-LULUCF.

All project emissions from REDD activities are calculated using the following equation:

$$PE_{REDDy} = PE_{ffy} + PE_{wbanry} + PE_{fy} + PE_{bby} + PE_{uthy} + PE_{ny} + PE_{wbfy}$$ Equation 15

Where:

PE_{REDDy} = Project emissions from REDD activities in year y; t CO_2e

PE_{ffy} = Project emissions from fossil fuel combustion in year y; t CO_2e

PE_{wbfy} = Project emissions from woody biomass removal for fire prevention activities in year y; t CO_2e

PE_{wbanry} = Project emissions from woody biomass removal during ANR activities in year y; t CO_2e

PE_{fy} = Project emissions from direct use of fertilizer in year y; t CO_2e

PE_{bby} = Project emissions from biomass burning in year y; t CO_2e

PE_{uthy} = Project emissions from unplanned timber harvesting in year y, t CO_2e

PE_{ny} = Project emissions from n activities in year y; t CO_2e

8.2.2 Project Emissions and Sequestration from ARR Activities

Project emissions and sequestration from ARR activities are quantified using CDM methodology *AR-AMS0007*. The net GHG removals by sinks must be calculated as below:

$$PS_{ARR} = \Sigma\Delta C_{c-pool,i,SP} * \frac{1}{\text{SP}} * S_{ARR,i} * 44/12$$ Equation 16

Where:

PS_{ARR}	=	Total project sequestration from ARR, tCO_2e
$\Delta C_{c\text{-pool},i,sp}$	=	Total carbon content of all the carbon pools within the sample plots in stratum i, (tC/smaple plot)
SP	=	Area of sample plot, ha
$S_{ARR,i}$	=	Area under stratum i in ARR in ha

The project proponent must also include losses of carbon where the ARR project scenario includes harvesting. This loss is in the form of the long-term average GHG benefit. The maximum number of GHG benefit should not exceed the total long-term average GHG benefit. VCUs may be issued until the long-term average is reached.

This calculation must be performed in accordance with the VCS rules.

8.3 Leakage Emissions (LE)

The project may include activities aimed to reduce leakage or provide alternative economic opportunities to the dependent communities in the project area which necessarily result in emissions. Such emissions must be accounted for and deducted from net emission reductions.

Leakage refers to the displacement of GHG emission sources from inside the project area to outside the project area due to emission reduction activities in the project area. The potential for all possible leakage must be identified and quantified and the project proponent must include LMZs as part of the overall project design.

The project proponent must address leakage by minimizing leakage risks through robust design of a project activity implementation to tackle the DoFCs and the inclusion of leakage inducing activities, and then discount the remaining leakage due to the project activity from the net carbon gain.

De minimis emissions from leakage are not required to be accounted for. The significance of leakage may be determined using the CDM A/R methodological tool *Tool for testing significance of GHG Emissions in A/R CDM Project Activities.*

Leakage occurring outside the host country are not required to be accounted for.

8.3.1 Leakage Management Zones

LMZ are assessed using the following steps:

1) LMZs must be estimated in order to assess leakage due to displacement of unplanned DoFC.
2) LMZs must be determined using socio-economic surveys and local intelligence

3) The assessment must be agent-centric and robust monitoring must be conducted to account for leakage.

4) All communities which are dependent on the project area for any kind of need must be monitored periodically or at least once at the time of verification through surveys. This will help in finding out what are the current requirements that are fulfilled with the help of the project activity and what are the remaining requirements for which the community has to depend on some other forest area.

8.3.2 Activity Shifting Leakage (ALEt)

The application of conservation practices in the project area may lead to undesirable and unintended movement of DoFC outside the project area leading to emissions of GHG due to deforestation and forest degradation of those areas. Where the shifting of activities increases the rate of DoFC, the related land use change, carbon stock/density changes and non-CO_2 emissions must be estimated and accounted as leakage.

The magnitude of activity shifting leakage will vary greatly across conservation projects. If neighbouring forested lands are easy to access and the DoFC are mobile, activity-shifting leakage is likely. Where forested land is not easily accessible or the DoFC are not mobile, the risk of activity-shifting leakage may be quite low.

Activity shifting leakage must be determined using the tools in Table 10 below.

Table 9: Sources of Leakage Emissions

Leakage source	Description
Fossil fuel combustion	Leakage due to all type of fossil fuel as a result of project activity must be calculated. Reference tool: CDM *Tool to calculate project or leakage CO_2 emissions from fossil fuel combustion*
Shifting of grazing and livestock production	Leakage due to shifting of grazing and livestock production as a result of the project activity must be accounted. Reference tool: CDM tool for the *Estimation of the increase in GHG emissions attributable to displacement of pre-project agricultural activities in A/R CDM project activity*
Shifting of agriculture activities	Leakage due to shifting of agricultural activities as a result of the project activity must be accounted. Reference tool: CDM tool for the *Estimation of the increase in GHG emissions attributable to displacement of pre-project agricultural activities in A/R CDM project activity*
Increased use of fertilizer	Leakage due to application of fertilizer causing significant N_2O emission from the project activity must be accounted. Reference tool: CDM tool for the *Estimation of direct nitrous oxide emission from nitrogen fertilization*

Unplanned timber harvesting	Leakage emission due to unplanned timber harvesting are required to be accounted. However, if the socio-economic survey found that there is no unplanned extraction of timber from the project area, then the leakage emissions from unplanned timber harvesting may be assumed to be zero. Reference tool: Through the selected socio-economic survey option and expert reviews
Biomass Collection	As per the general guidance on leakage in biomass project activities "the project participant must evaluate *ex-ante* if there is a surplus of the biomass residues in the region of the project activity, which is not utilised. If it is demonstrated (e.g., using published literature, official reports, surveys) at the beginning of each crediting period that the total/aggregated quantity of available biomass residues in the region (e.g., 50 km radius), is at least 25 per cent larger than the quantity of biomass residues that are utilised in the region including the project activity, then this source of leakage may be neglected. Otherwise, this leakage must be estimated and deducted from the emission reductions. Projects with more than one biomass residue type may, in principle, treat all relevant biomass residues as one type of biomass residue when estimating the surplus of the biomass in the region."[13]

8.3.3 Market Leakage (CLEt)

Market leakage must be quantified where, due to the conservation practices inside the project area, there is an impact on the supply chain of forest products which result in a shift of production of forest products elsewhere to fulfil the demand supply chain.

Market leakage emissions must be quantified by multiplying the net change in carbon stock with a leakage discount factor as follows:

$$CLE_y = LF_{md} \times \Delta C_{net,bsl,t} \qquad \text{Equation 17}$$

Where:

CLE_y,	=	Total market leakage as a result of REDD+ activities, in the year y since the start of the project activity, tCO_2e;
LF_{md}	=	The dimensionless leakage factor for market-effects calculations
$\Delta C_{net.bsl,y}$	=	Net greenhouse gas emissions in the baseline scenario in the year y since the start of the project activity, tCO_2e.

[13]http://cdm.unfccc.int/filestorage/e/x/t/extfile-20140515165832305-SSCWG44_annex11_Guideline_Leakage_in_biomass_ver04.0.pdf/SSCWG44_annex11_Guideline_Leakage%20in_biomass_ver04.0?t=b0R8bmZtejR5fDDWHSaVyD4kxwXkvvKoLsBw

Market leakage must be accounted for where unplanned timber harvesting is considered in the baseline emissions. Restriction to timber extraction may result in leakage. This may be attributed to (i) identified agents or (ii) unidentified agents.

In the case of identified agents, where timber extraction is/was a part of planned deforestation, the agent will have right over the forest land within the project area. All other forest land within the same management practice must be part of leakage management plan in such cases. If appropriate management plans exist to ensure no leakage occurs and it is demonstrated that there have been no marked increase in timber extraction in lands within the LMZ managed by the agent, leakage may be considered as zero. In case there is a marked increase in timber extraction from the forest lands within the LMZ (more than 5% as compared to the land management plan may be considered to be as a departure), then leakage must be calculated from the records of the actual activity on ground. In the absence (or difficulty in collection) of such information, the leakage discount factors that is to be used in case of unidentified agents (as explained in the next paragraphs) may be applied.

In the case of unidentified agents, comparable market leakage figures (from same forest type within the host country or comparable timber species within the host country) may be applied from scientific peer reviewed journals. As an alternative, a discount factor, which is estimated *ex-post* and revised along with baseline, may be applied to the net GHG changes associated with countermeasures that decrease timber harvest.

The leakage discount factor is estimated on the basis of a comparison between the ratio of merchantable biomass to total biomass across all strata in the project area in base year, and the ratio of merchantable biomass to total biomass within the area from where harvesting would likely be displaced to. The following discount factors may be applied for market leakage:

1) Countermeasures to decrease drivers have no or minimal effect on total timber harvest volume – apply discount factor 0%.
2) Countermeasures that decrease occurrences of harvesting (such as a moratorium), but eventually causing minimal reduction in harvested timber in the long run – apply discount factor 0.1.
3) In the case of countermeasures that substantially reduces harvest level permanently, three discount factors may be applied based on the availability of biomass which is of comparable use and quality in the LMZ as the mercantile biomass within the project area. The three discount factors are as follows:
    - If ratio of merchantable biomass to the total biomass in the leakage area is higher than that of the project area (more than 15%) - discount factor 0.2.
    - If ratio of merchantable biomass to the total biomass in the leakage area is similar to that of project area (within +/-15%) - discount factor 0.4.

- If ratio of merchantable biomass to the total biomass in leakage area is lower than the project area (less than 15%) - discount factor 0.7.

The leakage factor is determined by considering where due to the conservation project activity in the project area the country logging will be increased as a result of the decreased supply of the timber caused by the project. The market leakage may be neglected if it may be demonstrated that no market-effects leakage will occur within national boundaries, due to market leakage and annual extracted volumes increase is negligible within existing national boundary (emission is less than 5% of the total project's GHG emission reduction (i.e., *de minimis*) and illegal logging is absent in the project host country.

Leakage outside the host country is not required to be accounted.

8.3.4 Total Leakage

Total leakage is calculated as follows:

$$LE_y = CLE_y + ALE_y + LK_y \quad \text{Equation 18}$$

Where:

LE_y	=	Leakage emissions in year y, tCO_2e
CLE_y	=	Total market leakage emissions as a result of REDD+ activities, in the year y since the start of the project activity, tCO_2e;
ALE_y	=	Activity shifting leakage emissions in year ytCO_2e
LK_y	=	GHG emissions due to leakage of ARR activities, in year *y*; t CO_2-e

ARR project emissions due to activities such as vehicular emissions and fodder application are not to be accounted for. In line with *AR-AMS0007*, leakage emissions must be estimated as follows:

$$LK_y = LK_{AGRIC,y} \quad \text{Equation 19}$$

Where:

LK_y	=	GHG emissions due to leakage, in year *y*; t CO_2-e
$LK_{AGRIC,y}$	=	Leakage due to the displacement of agricultural activities in year *y*, as calculated in the CDM tool *Estimation of the increase in GHG emissions attributable to displacement of pre-project agricultural activities in A/R CDM project activity*; t CO_2-e

8.4 Calculation of Uncertainty

In every step of GHG emission quantification of a project activity, the level of uncertainty must be determined. Uncertainty includes measurement errors in the sample collection, inventory and laboratory processing. The project proponent must clearly state the uncertainty associated with the project activity and describe how much uncertainty must be addressed at what confidence level and must use the 2006 *IPCC Guidelines for National Greenhouse Gas Inventories*, Volume 4, AFOLU for uncertainty analysis. Tables 11 and 12 provide the appropriate guidance.

Table 11: Assessing Uncertainty While Accounting for Degradation

Accounting Type	Guidance Document
Assessing uncertainty while accounting degradation	2006 *IPCC Guidelines for National Greenhouse Gas Inventories*, Volume 4, AFOLU, Chapter 4, Section 4.2 or nationally accepted standard

Table 12: Assessing Uncertainty While Accounting for Deforestation

LULC Class	Guidance document
Forest land to cropland	2006 *IPCC Guidelines for National Greenhouse Gas Inventories*, Volume 4, AFOLU, Chapter 5, Section 5.3
Forest land to grassland	2006 *IPCC Guidelines for National Greenhouse Gas Inventories*, Volume 4, AFOLU, Chapter 6, Section 6.3
Forest land to settlement	2006 *IPCC Guidelines for National Greenhouse Gas Inventories*, Volume 4, AFOLU, Chapter 8, Section 8.3
Forest land to other lands	2006 *IPCC Guidelines for National Greenhouse Gas Inventories*, Volume 4, AFOLU, Chapter 9, Section 9.3

Where uncertainty is found to be less than zero, (i.e., if there is any possibility of NERs being underestimated) the uncertainty factor (UF) must be considered to be zero. In all other cases $UF_{projectREDD}$ is calculated using the guidances in tables 11 and 12 above.

8.5 Net GHG Emission Reduction and Removals

Net GHG emission reductions and removals are calculated as follows:

REDD

Net GHG emission reductions are removals from REDD activities are calculated using the following equation:

$$ER_{yREDD} = (BE_{yREDD} + BE_{yADD} - PE_{yREDD} - LE_y)(1 - \mathrm{UF}_{\mathrm{projectREDD}}) \quad \text{Equation 20}$$

Where:

ER_{yREDD} = Total GHG emissions reductions and removals in year y; tCO_2e
BE_{yREDD} = Baseline emissions from REDD activities in year y; tCO_2e
BE_{yADD} = Total additional baseline emissions in year y; tCO_2
PE_{yREDD} = Project emissions from REDD activities in year y; tCO_2e
LE_y = Leakage in year y; tCO_2e
$UF_{projectREDD}$ = Uncertainty (REDD)

ARR

Net GHG emission reductions and removals from ARR activities are calculated using the following equation:

$$ER_{yARR} = BE_{ARR} - PS_{ARR} - LK_t \quad \text{Equation 21}$$

Where:

ER_{yARR} = Net GHG removals by sinks, in year *t*; t CO_2-e
BE_{ARR} = Baseline net GHG removals by sinks, in year *t*; t CO_2e
LK_t = GHG emissions due to leakage, in year *t*; t CO_2e
PS_{ARR} = GHG emissions reductions and removals in year y; tCO_2e

Net GHG Emission Reductions/Removals

$$\mathrm{NER_y} = \mathrm{ER_{yREDD}} + \mathrm{ER_{yARR}} \quad \text{Equation 22}$$

Where:

NER_y = Net GHG emissions reductions and removals in year y; tCO_2e
ER_{yREDD} = GHG emissions reductions and removals by REDD project activities in year y; t CO_2e
ER_{yARR} = GHG emissions reductions and removals by ARR project activities in year y; t CO_2e

Buffer Contribution

Buffer credits are set aside to address risks of non-permanence and are determined using the net change in carbon stocks and the risk rating determined using the *AFOLU Non-Permanence Risk Tool*, using the following equations:

$$\mathrm{Buffer_y} = \Delta C_y \times \mathrm{RR_y} \quad \text{Equation 23}$$

$$\mathrm{VCU_y} = \mathrm{NER_y} - \mathrm{Buffer_y} \quad \text{Equation 24}$$

Where:

VCU_y = VCUs eligible for issuance in year y; tCO_2e

NER_y = Net GHG emissions reductions and removals in year y; tCO_2e

$Buffer_y$ = Buffer credits to be deposited in the AFOLU Pooled Buffer Account in year y; t CO_2e

ΔC_y = Net change in carbon stocks for REDD and ARR project activities in year y; t CO_2e

RR_y = Risk rating determined in year y

9 MONITORING

9.1 Data and Parameters Available at Validation

Data / Parameter	$BEF_{2,j}$
Data unit	Dimensionless
Description	Biomass expansion factor for conversion of stem biomass to above ground tree biomass for tree species *j*
Equations	4, 11
Source of data	Values from IPCC Good Practice Guidance for LULUCF (2003) Table 3A.1.10. Default values of biomass expansion factors (BEFs)
Value applied	IPCC GPG Default value
Justification of choice of data or description of measurement methods and procedures applied	BEF must be sourced from data on local ecological systems. In case of unavailability of this data, regional, national and international data must be used, in that order.
Purpose of Data	Project emissions and project sequestration
Comments	

Data / Parameter	CF_{Tree}
Data unit	$tCtd.m.^{-1}$
Description	Carbon fraction of dry matter for species of type *j*
Equations	4, 8, 9,11, 12
Source of data	Methodological tool: “*Estimation of carbon stocks and change in carbon stocks of trees and shrubs in A/R CDM project activities” Latest version.*

Value applied	A default value of 0.47 is used following the AR CDM methodological tool.
Justification of choice of data or description of measurement methods and procedures applied	To convert the dry biomass into carbon weight
Purpose of Data	Project emissions and project sequestration
Comments	To calculate CO_2 sequestered in equation $C_{Tree,\,t}$ = 44/12 * $B_{Tree,\,t}$ * CF_{Tree} where CF_{Tree} is the carbon fraction and C_{Tree} gives the CO_2 content in tonnes.

Data / Parameter	D_j
Data unit	t d.m. m^{-3}
Description	Density overbark of tree stem for tree species j.
Equations	4, 8, 11
Source of data	Good Practices IPCC Guidelines, 1996 and Published literature
Value applied	To be calculated
Justification of choice of data or description of measurement methods and procedures applied	*Dj* must be sourced from data on local ecological systems. In case of unavailability of this data, regional, national and international data must be used, in that order.
Purpose of Data	Project emissions and project sequestration
Comments	

Data / Parameter	$V_{TREE,j,p,i,t}$
Data unit	m^3
Description	Stem volume of trees of species j in sample plot p of stratum i at time t calculated using a volume Table or volume equation or allometric equations. In case a field analysis such as fractional downscaling has been conducted, this data need not be recorded.
Equations	4

Source of data	Field measurements for tree parameters (i.e. GBH, Height) measured in sample plot p of stratum i at time t. Volume equations of each species were taken from nationally accepted and published data. Not required in cases where fractional downscaling analysis is conducted.
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	$V_{TREE,j,p,i,t}$ must be sourced from data on local ecological systems. In case of unavailability of this data, regional, national and international data must be used, in that order.
Purpose of Data	Project emissions and project sequestration
Comments	

Data / Parameter	R_j
Data unit	Dimensionless
Description	Root-shoot ratio appropriate for biomass stock, for species *j*
Equations	4
Source of data	As per the field data analysis.
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Rj must be sourced from data on local ecological systems. In case of unavailability of this data, regional, national and international data (Values from IPCC Good Practice Guidance for LULUCF (2003) Table 3A.8 "*Average belowground to aboveground biomass ratio (root-shoot ratio, r) in natural regeneration by broad category (tons dry matter/ton dry matter)" may be considered as per the forest type.)* must be used, in that order.
Purpose of Data	Project emissions and project sequestration
Comments	

Data / Parameter	$S_{REDD,i}$
Data unit	Ha
Description	Land area on which REDD activities are planned under the project scenario for year t and in stratum i
Equations	6
Source of data	To be monitored from the records of project implementation and associated records such as KML files, vector files of land-use activities
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Follow the procedures described in Section 8.1.8
Purpose of Data	Project emissions and project sequestration
Comments	

Data / Parameter	$S_{ARR,i}$
Data unit	Ha
Description	Land area on which ARR activities are planned under the project scenario for year t and in stratum i
Equations	16
Source of data	To be monitored from the records of project implementation and associated records such as KML files, vector files of land-use activities
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Follow the procedures described in Section 8.2.2
Purpose of Data	Project emissions and project sequestration
Comments	Only to be included if ARR activities are implemented.

Data / Parameter	EF

Data unit	$g\ kg^{-1}$
Description	Emission factor of forest fires
Equations	10
Source of data	At the time of validation of baseline
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Follow the procedure described in Section 8.1.8.1, under Forest Fire
Purpose of Data	Project emissions
Comments	

Data / Parameter	Be
Data unit	Dimensionless
Description	Burning efficiency
Equations	10
Source of data	Surveys and/or government approved reports
Value applied	
Justification of choice of data or description of measurement methods and procedures applied	Follow the procedure described in Section 8.1.8.1, under Forest Fire
Purpose of Data	Project emissions
Comments	

9.2 Data and Parameters Monitored

Data / Parameter	ER_{yREDD}
Data unit	tCO_2e
Description	Net GHG emission reductions in year t. Here only REDD activities are being considered and only sinks based on REDD is to be recorded.
Equations	21

Source of data	Based on field inventories and implementation data. Where applicable data as per the SAR/LIDAR and /or Fractional downscaling is acceptable.
Description of measurement methods and procedures to be applied	Measurement methods involves appropriate stratification and sampling and field data collection of biomass and SOC.
Frequency of monitoring/recording	Before each verification
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Calculation of project emission reductions
Calculation method	
Comments	

Data / Parameter	BE_{yREDD}
Data unit	tCO_2e
Description	Baseline GHG emission reductions in year t. Here only REDD activities are being considered and only sinks based on REDD is to be recorded.
Equations	7, 20,
Source of data	Calculated
Description of measurement methods and procedures to be applied	N/A
Frequency of monitoring/recording	Before each verification
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Calculation of baseline emission
Calculation method	
Comments	

Data / Parameter	ER_{yARR}
Data unit	tCO_2e

Description	Net GHG removals by sinks, in year t. Here only ARR activities are being considered and only sinks based on ARR is to be recorded.
Equations	21
Source of data	Based on field inventories and implementation data
Description of measurement methods and procedures to be applied	The total stock of new plantations as per ARR activity is calculated. Carbon content in the stock is estimated over time. The rate of change of carbon stock of each stratum is added to arrive at the total change in carbon.
Frequency of monitoring/recording	Before each verification
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Project emissiosn and project sequestration
Calculation method	
Comments	

Data / Parameter	PS_{ARR}
Data unit	tCO_2e
Description	Project sequestration of GHG emission reductions in year t. Here only ARR activities are being considered and only sinks based on ARR is to be recorded.
Equations	22
Source of data	Calculated
Description of measurement methods and procedures to be applied	N/A
Frequency of monitoring/recording	Before each verification
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Calculation of project emission
Calculation method	
Comments	

Data / Parameter	BE_{ARR}
Data unit	tCO_2e
Description	Baseline GHG emission reductions in year t. Here only ARR activities are being considered and only sinks based on ARR is to be recorded.
Equations	22
Source of data	Calculated
Description of measurement methods and procedures to be applied	N/A
Frequency of monitoring/recording	Before each verification
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Calculation of baseline emission
Calculation method	
Comments	

Data / Parameter	$B_{Trees\text{-}ARR}$
Data unit	Number/dimensionless
Description	Number of baseline trees for the ARR component
Equations	16
Source of data	Field survey
Description of measurement methods and procedures to be applied	Data collected from field enumerations. Details of the trees are to be recorded appropriately.
Frequency of monitoring/recording	At the start of the project activity and every five years since the initial verification or before each verification.
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	To monitor carbon sinks
Calculation method	
Comments	

Data / Parameter	$Fuelwood_{forest}$
Data unit	t/year
Description	Amount of fuelwood collected from forests in a year.
Equations	8, 9
Source of data	Survey records, government documents
Description of measurement methods and procedures to be applied	The fuelwood collection pattern must be based on surveys and government data such as working plan and micorplans which have been approved. Separate fuelwood assessment studies also may be undertaken for this.
Frequency of monitoring/recording	At the start of the project activity and every five years since the initial verification or before each verification.
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Project and leakage emissions
Calculation method	
Comments	

Data / Parameter	$Fuelwood_{agri}$
Data unit	t/year
Description	Amount of fuelwood collected from agriculture land in a year.
Equations	8, 9
Source of data	Survey records, government documents
Description of measurement methods and procedures to be applied	The fuelwood collection pattern must be based on surveys and government data such as working plan and micorplans which have been approved. Separate fuelwood assessment studies also undertaken for this.
Frequency of monitoring/recording	At the start of the project activity and every five years since the initial verification or before each verification.
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Project and leakage emissions
Calculation method	

Comments	

Data / Parameter	FG_i
Data unit	$m^3 yr^{-1}$
Description	Annual volume of fuelwood species i gathered,
Equations	8, 9
Source of data	Surveys and/or government approved reports
Description of measurement methods and procedures to be applied	The fuelwood collection pattern must be based on surveys and government data such as working plan and micorplans which have been approved. Separate fuelwood assessment studies also may be undertaken for this.
Frequency of monitoring/recording	At the start of the project activity and every five years since the initial verification or before each verification.
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Project and leakage emissions
Calculation method	
Comments	

Data / Parameter	HTi
Data unit	$m^3 yr^{-1}$
Description	Annual volume of harvested timber, species i
Equations	11
Source of data	Surveys and/or government approved reports
Description of measurement methods and procedures to be applied	As per section 8.1.8.1, under the Unsustainable Timber Harvesting
Frequency of monitoring/recording	At the start of the project activity and every five years since the initial verification or before each verification.
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Project and leakage emissions

Calculation method	
Comments	

Data / Parameter	Ax_{fire}
Data unit	ha Yr^{-1}
Description	Area lost due to forest fire
Equations	10
Source of data	Surveys and/or government approved reports
Description of measurement methods and procedures to be applied	Area affected by forest fires may be ascertained from government reports. In the absence of such reports, or if these reports are inconclusive, FGDs may be conducted. The FGDs must be conducted of forest managerial staff
Frequency of monitoring/recording	At the start of the project activity and every five years since the initial verification or before each verification.
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Project and leakage emissions
Calculation method	
Comments	

Data / Parameter	*Fl*
Data unit	g m^{-2}
Description	Fuel loading per unit area
Equations	8, 9
Source of data	Surveys and/or government approved reports
Description of measurement methods and procedures to be applied	The fuelwood collection pattern must be based on surveys and government data such as working plan and micorplans which have been approved. Separate fuelwood assessment studies also may be undertaken for this.
Frequency of monitoring/recording	At the start of the project activity and every five years since the initial verification or before each verification.

QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Project and leakage emissions
Calculation method	
Comments	

Data / Parameter	B_w
Data unit	ha yr-^{1}
Description	Average biomass stock of forest areas
Equations	12
Source of data	Tables 3A.1.2, 3A.1.3, and 3A.1.4 of IPCC GPG LULUCF
Description of measurement methods and procedures to be applied	As per section 8.1.8.1, under Illegal Mining and Quarrying, Encroachment and Expansion of Subsistence Agriculture by Conversion of Forest Lands
Frequency of monitoring/recording	At the start of the project activity and every five years since the initial verification or before each verification.
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Project and leakage emissions
Calculation method	
Comments	

Data / Parameter	F_{biol}
Data unit	Dimensionless
Description	Fraction of biomass left to decay in forest (transferred to dead organic matter)
Equations	12
Source of data	Default value to be sourced from table 3A.1.11 of IPCC GPG LULUCF
Description of	Follow the procedure described in Section 8.1.8.1 given

measurement methods and procedures to be applied	under the Illegal Mining and Quarrying, Encroachment and Expansion of Subsistence Agriculture by Conversion of Forest Lands
Frequency of monitoring/recording	At the start of the project activity and every five years since the initial verification or before each verification.

Purpose of Data	Project and leakage emission
Calculation method	
Comments	

Data / Parameter	$Fire\ type$
Data unit	Dimensionless
Description	The cause of forest fire: Major categories being human induced or fire due to natural causes.
Equations	10
Source of data	Surveys and/or government approved reports
Description of measurement methods and procedures to be applied	Cause of forest fires may be ascertained from government reports. In the absence of such reports, or if these reports are inconclusive, FGDs may be conducted. The FGDs must be conducted of forest managerial staff
Frequency of monitoring/recording	At the start of the project activity and every five years since the initial verification or before each verification.
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Project and leakage emissions
Calculation method	
Comments	

Data / Parameter	$LC1y1 \rightarrow LC2Y2$
Data unit	ha
Description	Total land classified as stratum LC1 (ha) in time point y1 which has undergone transition to land classified as stratum LC2 (ha) in time point y2
Equations	3

Source of data	Remote sensing analysis
Description of measurement methods and procedures to be applied	Calculate based on the remote sensing classification and stratification procedures, as described under section 8
Frequency of monitoring/recording	At least once before every baseline update
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Determination of baseline scenario
Calculation method	It may be used for producing baseline transition matrix for new instances to be added into the project area.
Comments	

Data / Parameter	N_{LT}
Data unit	$hayr^{-1}$
Description	Land transition discounting factor due to scarcity of land
Equations	3
Source of data	Remote sensing analysis
Description of measurement methods and procedures to be applied	Described under section 8
Frequency of monitoring/recording	At least once before every baseline update
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Determination of baseline scenario
Calculation method	It may be used for producing baseline transition matrix for new instances to be added into the project area.
Comments	

Data / Parameter	$LC1_{Y1}$
Data unit	Ha
Description	Total area of LULC class or forest stratum 1 at time 1

Equations	2
Source of data	Remote sensing analysis
Description of measurement methods and procedures to be applied	Described under section 8.1.6
Frequency of monitoring/recording	At least once before every baseline update
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Project and leakage emissions
Calculation method	
Comments	

Data / Parameter	$area_{projectareawithharvest,projectscenario}(t,i)$
Data unit	ha yr^{-1}
Description	Size of strata i within the project area with harvest activities during year t under the project scenario.
Equations	16
Source of data	Remote sensing analysis
Description of measurement methods and procedures to be applied	This is relevant for ARR and LMZ
Frequency of monitoring/recording	At least once before verification
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Calculation of project emissions
Calculation method	
Comments	

Data / Parameter	$FW_{commercial}$
Data unit	$m^3 yr^{-1}$
Description	Annual volume of fuel wood gathering for commercial

	sale
Equations	8, 9
Source of data	1. Participatory rural appraisals 2. Recent (<10 yr) literature in the reference region 3. Recent (<10 yr) literature in an area similar to the reference region
Description of measurement methods and procedures to be applied	Estimate among participating communities and communities living in the leakage area.
Frequency of monitoring/recording	At the start of the project activity and every five years since the initial verification or before each verification.
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Calculation of project emissions
Calculation method	
Comments	

Data / Parameter	LE_y
Data unit	tCO_2e
Description	Leakage emission in year y
Equations	18
Source of data	Surveys and spatial analysis
Description of measurement methods and procedures to be applied	Estimate among participating communities and communities living in the leakage area.
Frequency of monitoring/recording	Before each verification and at the time of baseline update
QA/QC procedures to be applied	Standard SOPs recommended in the methodology must be applied. Review of monitoring records
Purpose of Data	Calculation of leakage emissions
Calculation method	
Comments	

9.3 Description of the Monitoring Plan

9.3.1 Monitoring Plan

Monitoring involves measuring and recording emissions, including carbon sequestered in the project area and any emissions due to leakage in the leakage area.

9.3.2 Methods of Monitoring

The project proponent may either use professional foresters or community members for carrying out monitoring of the carbon stock.

Extensive research on case studies[14] from around the world demonstrate that carbon stock estimates generated by community-based monitoring provide similar levels of uncertainty as estimates generated by an expert study. This demonstrates that trained and equipped members of local communities may collect accurate data. This also provides additional benefits to the project, as it was also found that involving community-based monitoring in REDD project can help in providing the opportunity of getting community members involved in the design and implementation of REDD projects. Additionally, use of technology like smart phones allows for real time data, and will likely also increase the efficiency of data collection.[15]

A further discussion of the benefits and challenges of community-based monitoring can be found in Box 1 below.

[14]http://forestcompass.org/case-studies/assessing-accuracy-and-cost-efficacy-community-based-monitoring-redd
http://forestcompass.org/case-studies/community-monitoring-chico-mendes-extractive-reserve-acre-brazil

http://forestcompass.org/case-studies/community-based-forest-monitoring-north-rupununi-guyana
[15]http://forestcompass.org/case-studies/community-based-forest-monitoring-north-rupununi-guyana

Box 1: Benefits and Challenges of Community-based Monitoring

Community monitoring helps communities take informed decision to participate in REDD policy dialogue, and allows communities to retain control over their forests. This leads to strengthening of forest management through increased coordination among project proponents, forest departments, communities and other relevant stakeholders. Participation will also help in spreading awareness about climate change impacts and mitigation activities. The following are examples of these activities:

- Offering way forward since the customary forest owners will help in generating scientific data; this will help the communities in making decisions related to forest management while retaining their control over land.
- Giving communities a sense of involvement and in assuring the safeguards of their rights providing
- Transparency and effectiveness in forest management;
- Respect for the traditional knowledge and rights of indigenous people;
- Full and effective participation of communities;
- The action which communities are asked and incentivized for is conservation of natural forests, biodiversity and emission reduction.

Through various case studies around the world it was found that the challenges in the community-based monitoring:

- Initial costs in community-based monitoring are high due to technology and capacity building of communities, though with time (i.e., from 2nd or 3rd monitoring period) the cost will considerably decrease. Also, considering travelling, wages and accommodation of costs of professional forestry experts could be outweighed by the capacity building costs.
- Low social cohesion and rights over common resources have been found to be a challenge for assessing drivers of forest change. Additionally, insufficient understanding of monitoring among neighbouring clans has been found to be one of the major challenges to resolve. Moreover, creating a common understanding about the monitoring procedure and benefit sharing within and between stakeholder groups is a time consuming process.
- Logistics for data collection in remote and uninhabited areas and information dissemination is difficult; therefore, it is favourable if community members undertake monitoring of the activity for the project within the proximity of their homes to decrease the logistical challenges.
- Communities may be clearly in a position to collect basic data from the forest, such as tree species, tree count and DBH. However, the measurements may not always be of high quality in the initial years. It is therefore necessary to have a parallel process to supplement the gaps in the basic data quality of the data collected by community(s).

Requirements of Communities for Performing Monitoring Activities

The following are requirements for monitoring activities:

- Well-designed training by forestry professionals.
- Good payment for their service in-cash or in-kind as required by the communities.
- Full and effective involvement of communities in design and implementation of REDD project.
- New and advanced technology like computers and smart phones may help further increase the community management of forest.

QA/QC in Community-Based Monitoring

A detailed project based risk-abatement plan must be developed before the start of the first monitoring activity. This must also be submitted to the verifier at the time of verification. The minimum frequency of monitoring must range from annually to every 5 years at maximum.

QA/QC Requirements of All Monitoring Methods

QA/QC of field data collected must be assured by the following:

- People involved in field measurement must be fully trained in field data collection and data analysis.
- List the names of all the field teams and the project leader and the dates of the training sessions.
- Record which teams have measured the sampling plots, record who was responsible for which task.
- Develop Standard Operating Procedures (SOPs) for each step of the field measurements and adhere to these at all times, both *ex-ante* and *ex-post.*
- Put a mechanism in place to correct potential errors or inadequacies in the SOPs by a qualified person.
- Verify that plots have been installed and measured correctly. Appropriate internal auditing mechanism must be established.

9.3.3 Monitoring Report Components

The following must be included in monitoring reports:

1) Land use change by deforestation
2) Forest degradation
3) Selected carbon pools
4) Biomass increase due to ANR

5) Leakage area
6) Project emissions
7) Loss events

The monitoring report must contain the information on activities listed below:

1) Changes in LULC in the project area, and leakage area, including a description of the remote sensing techniques; methods of analysis; accuracy assessment and validation used for assessing change in forest land i.e. deforestation and expansion of forest area.

2) Changes of forest cover within forest in the project area and leakage are, including a description of the remote sensing or stratification technique analysis method, accuracy assessment and validation to assess changes (increase or decrease) within the forest i.e. degradation.

3) The change in carbon stocks densities in the selected pool from project area in the project area and leakage area, including a description of the tier used, stratification techniques, techniques used for carbon change analysis, accuracy assessment to assess changes (increase or decrease) in the selected carbon pools in the project area.

4) The increase in the ANR area.

5) Project emissions from the selected carbon pools in the project and leakage area.

6) Loss events (if applicable).

7) Intervention activities in the project area and leakage area.

8) Monitoring of grouped project (if applicable).

9.3.4 Monitoring Steps

Changes in forest cover in the project area (and leakage belt for unplanned deforestation) must be measured before each verification as part of monitoring. All types of forest area need to be monitored for each reporting period. If resources are not sufficient to cover wall to wall coverage, a suitable method of sampling is recommended.

In cases where the project area is located within a region the jurisdictional program or any other VCS or UNFCCC registered MRV, the MRV data generated by the jurisdictional program must be used. In any other case, monitoring must be conducted by the project proponent or the outsourced to a third party having sufficient expertise to carry out the monitoring activities of the project.

All variables used at validation must remain the same. Where the project proponent uses new data and variables in the current fixed baseline period, the baseline must be recalculated using the new data and variables.

9.3.4.1 Monitoring LULC Change in the PA

Calculating actual forest change due to deforestation during the monitoring period, the project proponent must quantify and report the land use change due to deforestation in the PA.

Acquire RS data at the time of monitoring and compare it with the last acquired data and use the same procedure of analysis as used in the baseline for analysing LULC and forest cover. A minimum required selection of imagery and coverage, pre-processing (cloud shadow correction, geometric correction and radiometric correction) and classification of data will be as recommended in Section 8 in the methodology.

Several drivers cause forest degradation and loss of carbon stocks within forests but monitoring all of them with high accuracy is always a challenge. However, high resolution RS data and robust socio-economic surveys helps in achieving 90% - 95% of certainty in data collection. As discussed in Section 8, the gaps in the canopy caused by different drivers (unplanned) may be detected in imagery such as using frequently collected imagery through advanced analytical techniques available and acceptable at National level.

9.3.4.2 Drivers, Agents and Underlying Cause

The drivers, agents and underlying cause identified at the time of the start of the project must be re-assessed, verified and reported as discussed in Section 8.1.7 in the methodology.

9.3.4.3 Biomass Stock Density in LULC Class and Degraded Patch

As per the change quantified and reported, the project proponent must calculate the biomass change in the selected carbon pools in the PA as per the given procedures and tools used in Section 8.1.8 in the methodology.

9.3.4.4 Increase in Biomass Due to ARR

The project proponent must calculate the biomass increase in the current monitoring phase from the consecutive baseline or monitoring phase using biomass inventories. The increase in biomass must be calculated and reported against which the project proponent may claim credit. The project proponent must follow the monitoring procedure as described in *AR-AMS0007 A/R Small-scale Methodology: Afforestation and reforestation project activities implemented on lands other than wetlands*.

9.3.4.5 Monitoring of Project Emission

The resulting project emission due to the project activity must be monitored and accounted before each verification period using the same tools and procedures described in Section 8.2.

9.3.4.6 Monitoring of Leakage Area and LMZ

Increases in anthropogenic emission outside the project boundary due to activity shift or market leakage must be monitored and reported at each reporting period. Such emission must be deducted from the emission reduction to determine the net carbon benefit.

Two types of activities need to be monitored:

A) Increase in GHG emission or decrease in carbon stock due to activity shift or Market Leakage in the Leakage Area

Areas selected as leakage areas which are subjected to unplanned deforestation and forest degradation and cause significant decrease in carbon stock must be estimated and monitored before each verification.

B) Increase in GHG emission or decrease in carbon stock due to leakage prevention activities in the LMZ

In areas which are subject to LMZ for leakage prevention measures must be measured and accounted before each verification, this will offset the carbon emission due to the leakage in leakage area.

Monitoring ex-post Land use change and forest cover change in leakage area

Apply the same method used to monitor deforestation and degradation in the PA.

The reason of anthropogenic emission in the leakage area may be due to some external factor and not because of the project activity and if the project proponent may prove this by giving proper justification in the monitoring report, then the project proponent are allowed to adjust the baseline rate of emission reduction. In such case the rate of deforestation and degradation is assessed by calculating the rate in the RR through RS and then using this in the adjusted baseline.

Calculation of Leakage

Project proponent must apply the same procedures and tools used to calculate activity shift and Market leakage in Section 8.3 of the methodology.

In case if the Leakage area is located within a region within the jurisdictional program MRV, the MRV data generated by the jurisdictional program must be used.

In any other case monitoring must be done by the Project proponent or the outsourced third party having sufficient expertise to carry out the monitoring activities of the REDD project.

9.3.4.7 Monitoring intervention activities in the project area and LMZ

Project proponent must monitor and report the intervention activities taking place as a part of emission reduction program of the project activity. The project proponent must monitor and calculate the emission reduction through the approved standard methodologies of CDM or VCS.

The project proponent must exclude the energy efficient intervention activities sources which were already available in the baseline inside the project area and LMZ.

Also, once due to effective implementation of intervention activities or due to any other factor the project area is no longer in danger from the fuel wood emission, the benefit from the energy efficient intervention activities must be excluded. The effectiveness of the intervention activities or in an another word that the biomass stock in the project area is not depleting due to the fuel wood collection may be measured through socio-economic survey or any national data, local statistics, census, FRA reports, RS data, decrease in fuel wood price, trends showing tie and distance travelled by the fuel wood collectors.

9.3.4.8 Monitoring of the Sample Design and Stratification

The carbon stocks are monitored before or at each verification event by conducting a forest inventory using permanent or temporary sample plots. Re-measurement and re-assessment of sample plots is periodically needed and the results must be calculated and reported. Due to any unforeseen natural disaster and deforestation, the permanent sample plots have to be neglected and must not be considered during measurement of carbon stocks. Similarly, in order to measure the increase in forest stock, additional sample plots must be established in order to accurately account the forest carbon stocks. The Project proponent must use latest inventory method and emission factor to calculate ex-post emission reductions and removals.

9.3.4.9 Updates to Baseline Net GHG Removals by Sinks

The baseline must be re-measured and re-assessed after every 10 years and must be validated at the subsequent verification as per the VCS AFOLU Requirements.

9.4 Procedures for Managing Data Quality

The following are procedures that must be followed for managing data quality:

- The data collected must be documented and archived for a period of at least two years after the end of the last crediting period of the project activity.
- The PD must contain description about the Standard Operating Procedure (SOP)
- The SOP of field measurement and reporting must describe each step of field carbon and socio-economic measurement.
- The SOP document must contain the QA/QC procedure of field data measurement, monitoring steps and parameters and how to collect information and data with accuracy.

- Remedial action must be taken including:
  - Errors in the measurement procedure
  - Errors in stratification of forest
  - Effectiveness of intervention

QA/QC must contain (adapted from: MacDonald, 1994):

Precision: precision is a measure of mutual agreement among individual measurements or values of a variable taken under similar conditions.

Accuracy: accuracy is a degree of agreement between a measured value and the true or expected value of the variable.

Completeness: completeness is the percentage of measurement made, that are judged to be valid.

Representativeness: is the degree to which data accurately and precisely represent a characteristic of a population, variations at a sampling point, or an environmental condition. The program must be designed so that the samples collected are as representative as possible of the habitat or populations and a sufficient number of samples are collected.

Comparability: is a measure of the confidence with which one data set may be compared to another. Comparability is not quantifiable. However, it must be considered when designing sampling plans, analysis procedures, quality control and data reporting. Employing consistent data forms and survey protocols will maximize comparability.

- SOPs and QA/QC procedures for inventory operations, including field data collection and data management, must be calculated, recorded and used. SOPs from published handbooks at National level or from the "IPCC Good Practice Guidance for Land Use, Land-Use Change and Forestry 2003" Section 3.2.6,[16] is recommended.
- Data requirement may be found in the recommended tools in the methodology
- Data and parameters obtained from measurement must be monitored as required in the tools.

For further guidance on monitoring QA/QC, the project proponent may also consult:

- IPCC Good Practice Guidance for Land Use, Land-Use Change and Forestry.

Methodology for Electric Vehicle Charging Systems

Version 1.0

18 September 2018

Sectoral Scopes 1 & 7

This methodology was developed by the Climate Neutral Business Network, a project of Strategic Environmental Associates Inc, based upon generous support from the EV Charging Carbon Coalition (EVCCC).

The EVCCC seeks to open up access to the carbon capital markets for EV charging systems in order to strengthen their business case fundamentals and accelerate deployment. Beyond GM's business case development, founding members include:

- Electrify America LLC/Audi of America
- Exelon
- EVgo Services LLC
- Siemens
- Connecticut Green Bank
- Carbon Neutral Cities Alliance (including Portland, San Francisco, Seattle, Palo Alto, NYC, Minneapolis, Vancouver BC, Sydney, Adelaide, AU)

Table of Contents

1 SOURCES

This methodology uses the latest version of the following module:

- *VMD0049 Activity Method for Determining Additionality of Electric Vehicle Charging Systems*

This methodology used the latest version the following tools:

- CDM methodological tool *Demonstration of additionality of small-scale project activities*
- CDM methodological *Tool for the demonstration and assessment of additionality*

This methodology is based upon approaches used in the following methodology:

- CDM methodology *AMS-III.C. Emission Reductions by Electric and Hybrid Vehicles*[1].

2 SUMMARY DESCRIPTION OF THE METHODOLOGY

Additionality and Crediting Method	
Additionality	• Projects eligible to apply module VMD0049: Activity method • All other projects: Project method
Crediting Baseline	Project method

This methodology applies to the charging of electric vehicles (EVs) through EV charging systems, including their associated infrastructure, whose GHG emission reductions are achieved through the displacement of emissions from conventional fossil fuel vehicles used for passenger and freight transportation as a result of the electricity delivered by the project chargers.

This methodology provides easy-to-use monitoring parameters to quantify emission reductions, and also establishes default factors for the estimation of certain parameters for projects located in the United States and Canada as an alternative to project-specific calculations.

Finally, this methodology is applicable globally, and provides a positive list for determining additionality for regions with less than five percent market penetration of electric vehicles. The positive list is found in VCS module *VMD0049 Activity Method for Determining Additionality of Electric Vehicle Charging Systems.*

[1] This methodology was based on AMS.III.C.,version 15.0. See CDM website: https://cdm.unfccc.int/methodologies/index.html

3 DEFINITIONS

In addition to the definitions set out in VCS document *Program Definitions*, the following definitions apply to this methodology:

Applicable Fleets

The class of EVs eligible and technically able to charge at EV chargers associated with the project. For LDV projects, these applicable fleets comprise[2] BEVs and PHEVs for L1 and L2 chargers, and BEVs for DCFCs. For HDV projects, these applicable fleets comprise the MDV/HDV electric vehicles eligible to charge at the project's set of EV chargers.

Associated Infrastructure (AI)

Stationary battery storage devices[3] and dedicated renewable energy systems (e.g., solar or biofuel from on-site or other locations which use dedicated direct transmission lines) integrated as part of EV charging systems and managed by their control units. Associated infrastructure includes on-site battery storage systems which can store and dispatch electricity to and/or from any on-site renewable power systems, the grid, and/or the EV batteries. Associated infrastructure also includes the EV batteries themselves and thus includes EV vehicle-to-grid (V2G) and EV to on-site battery exchanges of electricity.

Associated Infrastructure Metering Systems

Systems used to track electricity flows between AI devices, whether using meters and/or associated measurement systems within or external to the EV charger. These may include upstream metering on the grid-side of the adequate metering system (e.g., where meters are installed grid-side of an on-site battery) and/or downstream metering (e.g., where metering takes place within the charger unit itself, downstream of the on-site battery).

Battery Electric Vehicle (BEV)

An EV which relies exclusively upon electricity delivered from an external EV charging system for its power in order to propel its motion

Charging Networks

A collection of charging systems which service any given applicable fleet

Closed Charging Networks

A collection of charging systems for which composition of the applicable fleet is constrained to a particular sub-set of EVs whose composition and operating characteristics of both the applicable

---

[2] There may be a very few PHEVs which also have the plug capability to charge at DCFCs (e.g., Mitsubishi Outlander); these are considered de minimis. Similarly, the BMW i3 REX (with range extender) is technically a PHEV, but only 5% of i3s use the range extender in practice. Moreover, Argonne National Laboratory and California classify the REX as a BEV, and therefore it is included in the BEV category for default factor calculation purposes in this methodology.

[3] For larger powered systems (e.g., 150kw, 320kw), stationary battery systems may become a more typical integrated part of the EV charging system infrastructure over time (e.g., to mitigate demand peak charges from utilities); they are controlled by the charging system's control unit and are located close to the site within the charging system's metering to the utility.

and comparable fleets can be specifically identified and documented (e.g., a transit agency's e-bus charging network)

Comparable Fleets
Those fossil-fuel vehicles whose travel characteristics have been defined to be comparable to the EVs in each applicable fleet as determined in Section 4 below

DC Fast Charger (DCFC)
A charger which provides direct current charging (typically at 200-1000V) from an off-board[4] charger with a power rating above 11kw. Typical DCFC ratings are 50kw, with the newest systems for passenger vehicles in the 150kw and 320 kw ranges. DCFC classifications are defined as:

- DCFC 50kw: capable of delivering maximum power from 11kw to 62.5kw
- DCFC 100kw: capable of delivering maximum power from 63kw to 110kw (i.e., 200A)
- DCFC 150kw: capable of delivering maximum power from 111kw to 160kw (i.e., 200A@800V or 350A@400V, some with cooled connectors)
- DCFC 320kw: capable of delivering maximum power from 161kw and 360kw (i.e., cooled connectors)
- DCFC 500kw: capable delivering maximum power from 361kw and above (i.e., different connectors)

Where no kw classification is specified in this methodology, DCFC includes all classes defined above.

Dedicated Renewable Energy
Renewable power (e.g., solar, wind, and bio-fuel) supplied either from sources on-site within the associated infrastructure of the project, or received from a dedicated supply source via a direct transmission line. These renewable sources represent a distinct segment, differentiated from the renewable electricity supplied via the broader grid. These dedicated renewables may also be delivered in part for use on the main grid.

Electric Vehicle (EV)
Vehicles, including BEVs and PHEVs, spanning both passenger cars, LDVs and HDVs, powered by the external electricity sources of charging systems. EVs do not include hybrid-only vehicles since they do not consume electricity from externally generated sources.

[4]See SAE standards:
http://grouper.ieee.org/groups/earthobservationsSCC/IEEE_SAE_J1772_Update_10_02_08_Gery_Kissel.pdf

EV Chargers

Charging dispensers and their metering systems including L1, L2 and/or DCFC units which provide electricity to EVs within an applicable fleet and which may form part of an EV charging system

EV Charging Systems

A set of EV chargers including L1, L2 and/or DCFC and their associated infrastructure (if any) which, when located at a given charging site, provide electricity to EVs within a given applicable fleet, and which may form part of a charging network

EV Market Share

The number of EVs on the road within a geographic region, expressed as a percentage of total vehicles on the road within a geographic region, segmented for applicable fleets across LDV and HDV sectors

Heavy Duty Vehicles (HDV)

Vehicles consistent with definitions provided by the governing national regulatory system(s) of the project location. HDVs may also include medium duty vehicles (MDVs). These must be consistent with the data sources used in the standardized tests and default ER factors applied, if any[5].

Kwh/100 Mile Ratings

Ratings as provided by credible national government/regulatory sources which establish the kwh consumed to travel 100 miles, sourced for each EV model within applicable fleets, and used to calculate the weighted average Applicable Fleet's Electricity Consumption (AFEC) rating

Level 1 Charger (L1)

A charger which provides 120V alternating current charging services to the vehicle's on-board charger with a power rating up to 1.8kw

Level 2 Charger (L2)[6]

A charger which provides 240V alternating current charging services to the vehicle's on-board charger with a power rating up to 20kw (typically from 3.3kw to 6.6 kw)

Light Duty Vehicles (LDV)

Cars and trucks consistent with definitions provided by the governing national regulatory system(s) of the project location. These must be consistent with the data sources used in the standardized tests and default ER factors applied, if any[7].

---

[5] For example, in the United States, HDVs are specified as including both HDVs and those MDVs with Gross Vehicle Weight Ratings (GVWR) of more than 14,000lbs (typically from class 4 and above), consistent with the IHS Markit data sources applied in the development of the default factors. HDV vehicles include both e-buses and e-trucks.

[6] Note that, in London UK, L2 chargers have been referenced as fast chargers. And, DCFCs are referenced as rapid chargers. Regardless of nomenclature, the chargers will be defined against the technical criteria provided in this methodology.

[7] For example, in the United States, LDVs are specified as including vehicles with) GVWR up to and including 14,000lbs, (classes 1, 2, and 3) and must therefore include those Medium Duty Vehicles (MDVs) up to this same

Medium and Heavy Duty Electric Vehicle (HDV EV)
Medium duty and heavy duty vehicles (collectively defined as *HDV*) comprising both BEV and PHEV HDV electric vehicles, including e-buses and e-truck categories, which rely upon electricity delivered from external EV charging systems for their power

Miles per gallon (MPG) ratings
Mile per gallon ratings as provided by credible national government/regulatory sources establish the miles traveled per gallon of fuel consumed, for those fossil fuel vehicles deemed comparable per Section 4 to the EV's applicable fleet[8]

Open Charging Networks
A charging network where the applicable fleet is not constrained to a particular sub-set of EVs whose composition and operating characteristics of both the applicable and comparable fleets can be identified and documented, as with a closed charging network

Plug-in Hybrid Electric Vehicle (PHEV)
A vehicle combining an internal combustion engine and one or more electric motors, which must also be capable of receiving delivered electricity by plugging into an external EV charging system for its power in order to propel its motion

Private Charging Networks
Charging systems where charger access is limited to a defined applicable fleet. For example, residential chargers would be considered private since access is restricted, as would a city's chargers if their use was limited to the charging of the city's own EV fleet vehicles. Private refers to the limited degree of access to the chargers, not the charging system's owner's status (since public city chargers can use private charging networks). The composition of those EVs accessing the network need not be known (that is, both open (e.g., residential) and closed (e.g., e-bus transit agency charging) networks can be private if access is limited).

4 APPLICABILITY CONDITIONS

This methodology applies to project activities which install EV charging systems, including their associated infrastructure, in order to charge EV applicable fleets whose GHG emission reductions are achieved through the displacement of conventional fossil fuel vehicles used for passenger and freight transportation as a result of the electricity delivered by project chargers.

weight limit, consistent with the IHS Markit data sources applied in the development of the default factors. This 14,000lbs GVWR values is based upon definitions used and supplied by IHS Markit data for light duty vehicles, whose data forms the basis for most US EV market analysis publications. Commercial applications in the 8500-14000 lb Class 2b and 3 are a de minimis proportion of total LDV's. See also: http://changingears.com/rv-sec-tow-vehicles-classes.shtml and https://www.afdc.energy.gov/data/10380 Lighter MDV's include the types of vehicles which also use the main LDV charging networks (e.g., retirement home vans).

[8] For countries using other metrics (e.g., ratings in Europe for CO2 per km), conversion guidance is given in Section 8 below.

Projects must comply with all applicability conditions set out below:

1) The applicable fleets of projects applying this methodology are limited to all LDV BEVs and PHEVs[9], and HDV EVs. For LDV projects, these applicable fleets comprise[10] BEVs and PHEVs for L1 and L2 chargers, and BEVs for DCFCs. For HDV projects, these applicable fleets comprise MDV/HDV electric buses and trucks, both BEV and PHEV, eligible to charge at the project's set of EV charging systems.

2) Project proponents must demonstrate that the EV models comprising the applicable fleet of the project are comparable to their conventional fossil fuel baseline vehicles using the following means:

    - Project and baseline vehicles belong to the same vehicle category (e.g., car, motorcycle, bus, truck, LDV, MDV, HDV);

    - Project and baseline vehicles have comparable passenger/load capacity (comparing the baseline vehicle with the respective project vehicle).

    Note that where project proponents apply the baseline emission default factors for MPG and AFEC determined for the US and Canada, this comparability requirement between applicable and comparable fleet models has already been completed and satisfied.

3) In order to demonstrate that double counting of emission reduction will not occur, the project proponent must maintain an inventory of EV chargers included in the project, including their L1/L2/DCFC classifications and unique identifiers; other measures may include disclosure of credit ownership to EV drivers. Double counting relative to any issued GHG credits[11] from projects that introduce EV fleets[12] will be addressed using the emission reduction discount adjustments in Section 8.4 below[13]. Where associated infrastructure and/or renewable power (on-site and/or direct transmission) are included in an EV charging system, this must be referenced and described in the charging system's inventory. Project documentation must also include the following for each EV charger:

    - Classification using the performance voltage, AC/DC basis and kw power specifications given for L1, L2 and DCFC 50/100/150/320/500 definitions

---

[9] Hybrid-only vehicles, which do not have batteries capable of receiving electricity to propel their motion, are not eligible under this methodology

[10] There may be a very few PHEVs which also have the plug capability to charge at DCFCs (e.g., Mitsubishi Outlander); these are considered de minimis. Similarly, the BMW i3 REX (with range extender) is technically a PHEV, but only 5% of i3s use the range extender in practice. Moreover, Argonne National Laboratory and California classify the REX as a BEV, and therefore it is included in the BEV category for default factor calculation purposes in this methodology.

[11] Credits for GHG emission reductions issued by a GHG program such as the American Carbon Registry (ACR) Climate Action Reserve (CAR), Verified Carbon Standard (VCS), or the UNFCCC's Clean Development Mechanism (CDM).

[12] For example, projects that apply CDM methodology AMS.III.C.

[13] Double counting related to any jurisdictional emission trading systems or commitments (e.g., cap-and-trade programs, etc.) must still be assessed per the VCS rules.

- Unique identifiers, including the geo-spatial coordinates and one other unique reference such as NEMA codes, customer codes, equipment serial numbers, charger ID codes, or AFDC ID codes

4) This methodology is applicable to EV charging systems utilizing AI to provide electricity to and from EVs, on-site batteries and renewables[14] under the condition that the AI must include adequate metering systems (e.g., meters/sub-meters and/or associated measurement systems). These metering systems must measure and accurately trace all electricity deliveries and receipts from all such interrelated associated infrastructure sources. This includes electricity sourced from/returned to the grid, dedicated renewable energy generated on-site (including RE sourced from direct transmission lines), on-site storage batteries, and/or the EV's on-board battery.

5) Projects with estimated annual emission reductions of over 60,000 tCO_{2e}[15] (large-scale) are permitted where project proponents can demonstrate that the project is located in a country with credible national data sources for GHG emission calculations. Otherwise, projects are limited to annual emission reductions equal to or under 60,000 tCO_{2e} (small-scale). Projects located in Annex I and II countries, and countries referenced by EIA data sources, are automatically eligible to be of any scale. All regions listed in module *VMD0049 Activity Method for Determining Additionality of Electric Vehicle Charging Systems* meet these criteria and thus are not limited in scale.

6) Project proponents must demonstrate proof of ownership of emission reductions which may be achieved through the following:

    - With the charging system owners through contractual agreements, terms of service, utility program participation rules, or other means, and/or

    - With EV drivers through disclosure of credit ownership (e.g., through dispenser notices, screen displays, terms of service, etc.).

5 PROJECT BOUNDARY

The project boundary is comprised of the following:

1) The applicable fleets for the project EV chargers;
2) The geographic boundaries where the EV charging systems are located;
3) The EV charging systems of the project activity including their electricity supply sources and associated infrastructure.

The greenhouse gases included in or excluded from the project boundary are shown in Table 1 below.

[14] AI may store and dispatch electricity both to and from multiple sources, both on site and regionally.
[15] The small and large scale boundary was drawn from CDM methodology AMS-III.C.

Table 1: GHG Sources Included In or Excluded From the Project Boundary

Source		Gas	Included?	Justification/Explanation
Baseline	Fossil fuel combustion of vehicles displaced by project activities	CO_2	Yes	Main emission source
		CH_4	Optional	May be excluded for simplification
		N_2O	Optional	May be excluded for simplification
		Other	No	Not Applicable
Project	Electricity consumption via grid	CO_2	Yes	Main emission source
		CH_4	Optional	May be excluded for simplification. Where included in the baseline, source must also be accounted in project emissions.
		N_2O	Optional	May be excluded for simplification. Where included in the baseline, source must also be accounted in project emissions.
		Other	No	Not Applicable.
	Renewables via on-site/direct transmission	CO_2	Yes	Main emission source
		CH_4	Optional	May be excluded for simplification. Where included in the baseline, source must also be accounted in project emissions.
		N_2O	Optional	May be excluded for simplification. Where included in the baseline, source must also be accounted in project emissions.
		Other	No	Not Applicable
	On-site battery storage	CO_2	Yes	Main emission source
		CH_4	Optional	May be excluded for simplification. Where included in the baseline, source must also be accounted in project emissions.
		N_2O	Optional	May be excluded for simplification. Where included in the baseline, source must also be accounted in project emissions.
		Other	No	Not Applicable
		CO_2	Yes	Derived emission source[16]

[16] The EV battery is a derived emission source based upon the kwh received from the grid, dedicated renewables and on-site battery. It does not have a separate independent emissions factor since any kwh the EV battery returns to the grid or the on-site battery are netted out (in NEC and NECT) against the kwh delivered to the EV from these sources using their respective emissions factors. See Equations 7, 8, and 9 and Appendix 2.

Source		Gas	Included?	Justification/Explanation
	EV battery storage in vehicle	CH_4	Optional	May be excluded for simplification. Where included in the baseline, source must also be accounted in project emissions.
		N_2O	Optional	May be excluded for simplification. Where included in the baseline, source must also be accounted in project emissions.
		Other	No	Not Applicable

6 BASELINE SCENARIO

The baseline scenario is the operation of comparable fleets (the comparability of baseline and project applicable fleet vehicles to be demonstrated as per indicators set out in applicability conditions in Section 4 above), that would have been used to provide the same transportation service in the absence of the project.

7 ADDITIONALITY

Project proponents applying this methodology must determine additionality using the procedure described below:

Step 1: Regulatory Surplus

Project proponents must demonstrate regulatory surplus in accordance with the rules and requirements regarding regulatory surplus set out in the latest version of the *VCS Standard*.

Step 2: Positive List

The applicability conditions of the latest version of VCS module *VMD0049 Activity Method for Determining Additionality of Electric Vehicle Charging Systems* represent the positive list. The positive list was established using the activity penetration option (Option A in the *VCS Standard*). Projects that meet all applicability conditions of this methodology and VCS module *VMD0049 Activity Method for Determining Additionality of Electric Vehicle Charging Systems* are deemed additional.

Step 3: Project Method

Where Step 2 is not applicable, project proponents may apply the following[17]:

- Where the project is small-scale, the project proponent must demonstrate that the project activity would otherwise not be implemented due to the existence of one or more

[17] When applying either tool, regardless of which entity is implementing the project, project proponents may demonstrate that barriers apply for charging service providers and/or their associated partners (e.g., installation customers, utilities, end-users, charging system network service providers, and EV manufacturer/retailer).

barrier(s) listed in the latest version of the CDM methodological tool *Demonstration of additionality of small-scale project activities*.

- Where the project is large-scale, the project proponent must apply the latest version of the CDM *Tool for the demonstration and assessment of additionality*.

8 QUANTIFICATION OF GHG EMISSION REDUCTIONS AND REMOVALS

8.1 Baseline Emissions

Baseline emissions are calculated by converting the electricity used to charge project applicable fleet vehicles at the EV chargers into distance travelled, and multiplying this by the emission factor for fossil fuels used by baseline comparable fleet vehicles to travel the same distance. Baseline emissions must be calculated as follows:

$$BE_y = \sum_{i,f} ED_{iy} * EF_{ify} * 100 * IR_i^{y-1} / (AFEC_{iy} * MPG_{iy}) \quad (1)$$

Where:

BE_y = Baseline emissions in year *y* (tCO_2e)
$ED_{i,y}$ = Electricity delivered by project charging systems serving applicable fleet *i* in project year *y* (kwh)
$EF_{j,f,y}$ = Emission factor for the fossil fuel *f* used by comparable fleet vehicles *j* in year *y* (tCO_2e/gallon)
$IR_{i,}$ = Technology improvement rate factor for applicable fleet *i*
$AFEC_{i,y}$ = Weighted average electricity consumption per 100 miles rating for EVs in applicable fleet *i* in project year *y* (kwh/100 miles)
$MPG_{i,y}$ = Weighted average miles per gallon rating for the fossil fuel vehicles comparable to each EV in applicable fleet *i*, in project year y (miles per gallon)

Default values for $MPG_{i,y}$, $AFEC_{i,y}$, $EF_{j,f,y}$, and $IR_{i,}$ across both LDV and HDV applicable fleets can be found in the parameter tables in Section 9.1 below for the United States and Canada.

The weighted average electricity consumption per 100 miles rating for EVs in applicable fleet *i,* is calculated as follows:

$$AFEC_{iy} = \sum_a (EV_{aiy} * EVR_{aiy}) / \sum_a EVR_{aiy} \quad (2)$$

Where:

$AFEC_{i,y}$ = Weighted average electricity consumption per 100 miles rating for EVs in applicable fleet *i* in project year *y* (kwh/100 miles)
$EV_{a,j,y}$ = Electricity consumption per 100 miles rating for model *a* EV in applicable fleet *i* in project year *y* (kwh/100 miles)
$EVR_{a,j,y}$ = Total number of model *a* EV in applicable fleet *i* on the road by project year *y* (cumulative number of EVs)

The weighted average miles per gallon rating for the comparable fleet associated with each applicable fleet *i*, is calculated as follows:

$$MPG_{iy} = \sum_a (MGP_{aiy} * EVR_{aiy}) / \sum_a EVR_{aiy} \quad (3)$$

Where:

$MPG_{i,y}$ = Weighted average miles per gallon rating for fossil fuel vehicles comparable to each EV in applicable fleet *i* in project year *y* (miles per gallon)

$MPG_{a,j,y}$ = Mile per gallon rating for the fossil fuel vehicle model deemed comparable to each EV model a from applicable fleet *i* in project year *y* (miles/gallon)

$EVR_{a,i,y}$ = Total number of EV models within applicable fleet *i* on the road by project year y (cumulative number of EVs)

Guidance regarding the calculation procedures for $AFEC_{i,y}$ and $MPG_{i,y}$ and their associated parameters is given in the parameter tables in Section 9.2 and applicability condition #2.

Further details for the calculation of the default values for $MPG_{i,y}$, $AFEC_{i,y}$, can be found in Appendix 1 and the accompanying *Default MPG and AFEC Workbook* on the Verra website.

8.2 Project Emissions

Project emissions include the electricity consumption associated with the operation of the applicable fleet and must be calculated as follows:

$$PE_y = \sum_{ij} EC_{ijy} * EFkw_{ijy} \quad (4)$$

Where:

PE_y = Project emissions in year *y* (tCO_2e)

$EC_{i,j,y}$ = Electricity consumed by project chargers sourced from region *j* serving applicable fleet *i* in project year *y* (kwh/year)

$EFkw_{i,j,y}$ = Emission factor (average) for the electricity sourced from region *j* consumed by project charging systems serving applicable fleet *i* in year *y* (tCO_2e/kwh)

Where "time-of-day" estimates (i.e., estimates segmented by time periods within a single 24-hour day) for project emissions are available, Equation 5 may be applied, thus replacing Equation 4, provided that:

1) There are no time periods in which electricity is provided but not accounted for within *PEy* (i.e., the sum of all such time-of-day time periods *t* equals 24 hours in any given full day within the project).

2) Time-of-day estimates for electricity emission factors $EFkwTOD_{i,j,t,y}$ are drawn from credible, applicable sources and are provided on at least an hourly basis (e.g., the regional Independent System Operation (ISO) or applicable utility generation sources).

$$PE_y = \sum_{ijt} ECTOD_{ijty} * EFkwTOD_{ijty} \quad (5)$$

Where:

PE_y = Project emissions in year *y* (tCO_2e)

$ECTOD_{i,j,t,y}$ = Electricity consumed by project chargers sourced from region *j* serving applicable fleet *i* during time of day period *t* in project year *y* (kwh/time period *t*)

$EFkwTOD_{j,,j,t,y}$ = Emission factor for the electricity sourced from region *j* consumed by project chargers serving applicable fleet *i* during time of day period *t* in year *y* (tCO_2e/kwh)

Where ISO does not provide greenhouse gas emission factors on an hourly basis in region *j*, but does provide fuel consumption data for electricity generation on an hourly basis, $EFkwTOD_{ji,j,t,y}$ may be estimated on a weighted average basis as follows:

1) Projects must combine the hourly fuel consumption figures (typically given as the percentage of each type of fuel consumed that hour (e.g., 50% coal, 50% natural gas)) with the emission factors for these same fuels to create a weighted average emission rate for each hourly period.

2) Emission rates for each fuel must be drawn from the same source (e.g., ISO) or consistent publication sources for region *j.*

Equations supporting these fuel-consumption based time-of-day calculations for $EFkwTOD_{j,,jy}$ are given in the equation below:

$$\mathrm{EFkwTOD_{ijty}} = \sum_{\mathrm{f}} \mathrm{F\%_{ijtfy}} * \mathrm{EFkwF_{ijtfy}} \quad (6)$$

Where:

$EFkwTOD_{j,j,t,y}$ = Emission factor for the electricity sourced from region *j* consumed by project chargers serving applicable fleet *i* during time of day period *t* in year *y* (tCO_2e/kwh)

$EFkwF_{i,j,t,f,y}$ = Emission factor applicable for the fuel type *f* used to generate the kwh sourced from region *j* consumed by project charging systems serving applicable fleet *i* during time of day period t in year y (tCO_2e/kwh)

$F\%_{i,j,t,f,y}$ = Percentage of fuel type *f* used to generate the kwh during each time of day period *t*, sourced from region *j* and consumed by EV charging systems serving applicable fleet *i* in year *y* (%)

Where projects include associated infrastructure within their charging systems, project emissions must be quantified for all such sources *s* following Equation 7, which must replace Equation 4, where the following applies:

1) The electricity emissions factor for the on-site battery must be calculated using the net weighted average of the grid and on-site renewable emission factors as provided in Equation 8 below.

2) The charging system's metering system must adequately and accurately measure and trace such net electricity kwh provided to the charging system (i.e., deliveries minus receipts) from all electricity sourced from/returned to the grid and the dedicated renewables. This includes, for example, electricity sourced from the grid, dedicated renewables (e.g., on site) and delivered to the EV directly and/or via on-site batteries, net of kwh returned back to such sources from the EV batteries[18]. See Appendix 2 for guidance on adequate metering systems.

$$PE_y = \sum_{ijs} NEC_{ijsy} * EFkwAI_{ijsy} - \sum_{ij} LEC_{ijy} * EFkwonsitebatt_{ijy} \quad (7)$$

Where:

PE_y	= Total project emissions in year y (tCO_2e)
$NEC_{i,j,s,y}$	= Electricity consumed by EV charging systems supplied from associated infrastructure source *s* net of any kwh EV/charger returned to this same source within region *j* serving applicable fleet *i* in project year *y* (kwh/year)
$EFkwAI_{j,,j,s,y}$	= Emission factor for the electricity from each associated infrastructure source *s* within region *j* consumed by project chargers serving applicable fleet *i* in year *y* (tCO_2e/kwh)
$LEC_{j,,j,y}$	= Electricity provided to the grid and/or building from on-site storage battery within region *j* serving applicable fleet *i* in project year *y* (kwh/year)
$EFkwonsitebatt_{i,j,y}$	= Emission factor for the electricity from the on-site battery associated infrastructure source *s* within region *j* consumed by project charging systems serving applicable fleet *i* in year *y* (tCO_2e/kwh)

Where projects include associated infrastructure, the emission factor for electricity from on-site battery associated infrastructure must be calculated using the net weighted average of the grid and on-site renewable emission factors as follows:

$$EFkwonsitebatt_{ijy} = \sum_z ECB_{ijzy} * EFkwAIZ_{ijzy} \quad (8)$$

[18] It should be noted that metering systems for associated infrastructure can include "downstream" meters close to the EV, such as those provided by DCFC onboard meters, and "upstream" meters, located grid-side such as meters monitoring kwh delivered to the on-site batteries. Guidance provided in Appendix 2 is designed to assist the application of Eq 7 given the particular features of a project's adequate metering systems.

Where:

$EFkwonsitebatt_{i,j,y}$	= Emission factor for the electricity from the on-site battery associated infrastructure source *s* within region *j* consumed by project charging systems serving applicable fleet *i* in year *y* (tCO_2e/kwh)
$ECB_{i,j,z,y}$	= Electricity consumed by on-site battery from associated infrastructure sources *z*, which comprise only the grid-connected and dedicated renewable sources, within region *j* serving applicable fleet *i* in project year *y* (kwh/year)
$EFkwAI\text{-}Z_{i,j,z,y}$	= Emission factor for the electricity from the associated infrastructure sources *z*, which comprise only the grid-connected and dedicated renewable sources, within region *j* consumed by on-site batteries serving applicable fleet *i* in year *y* (tCO_2e/kwh)

Guidance for sourcing the emission factors for the other associated infrastructure sources *s* is provided in the monitoring parameter boxes found in Section 9; guidance regarding adequate metering systems is found in Appendix 2.

Where projects include associated infrastructure and estimates for time-of-day project emissions are available, Equation 9 may be followed, thus replacing Equations 4, 5 and 7, provided that:

- There are no time periods in which electricity is provided but not accounted for within *PEy* (i.e., the sum of all such time-of-day time periods, t, equals 24 in any given full day within the project)
- Time-of-day estimates for electricity emission factors, $EFkwTODAI_{j,j,s,t,y}$ are drawn from credible, applicable sources (e.g., the regional ISO or applicable utility generation source).
- Equation 7 must be applied to calculate $EFkwTODAI_{j,j,s,t,y}$ where electricity generation's hourly fuel consumption data is relied up to provide time-of-day emission rates for each associated infrastructure source (e.g., grid-derived electricity).
- The electricity emissions factor for the on-site battery must be calculated using the net and time weighted average of the grid and on-site renewable emission factors given in Equation 8.
- The provisions regarding the charging system's adequate metering systems as given for Equation 7 and 8 (including guidance offered in Appendix 2) also apply for Equation 9 in order to adequately and accurately measure and trace net electricity consumption (NECT) from sources *s*, but are applied during each time-of day period *t* provided that:
    - For time-of-day applications of associated infrastructure calculations pertaining to the NECT for an on-site battery's kwh delivered to the EV charger, metering must be applied "upstream", on the grid-side of the on-site battery. That is, for the calculation of NECT for an on-site battery, Equation 9 will, using upstream meters, calculate the kwh delivered to EV chargers via the on-site battery from grid and/or dedicated renewable sources during the time of day period t taking

into account *when* these kwh are actually delivered *to the on-site battery* (i.e., not when delivered from this battery to the EV charger), since the GHG impacts for these kwh arise on the grid system when they are first delivered into this associated infrastructure system (that is, are delivered to the on-site battery)

- For these applications, kwh supplied by the EV to the on-site battery can be set aside (since they return to the EV at a later date) unless, during a given time period *t*, the LECT less the kwh received by the on-site battery from grid and renewable sources less the on-site battery's stored kwh is greater than zero – that is, LECT is so large that it must have drawn upon the kwh delivered to the on-site battery from the EV

In the context of these NECT calculations for the on-site battery, note that the electricity supplied from the grid to the EV charging system directly, and the electricity supplied by the EV back to the grid during any time period *t* are considered separately in the calculation of NECT for the grid.

$$PE_y = \sum_{ijst} NECT_{ijsty} * EFkwTODAI_{ijsty} - \sum_{ijt} LECT_{ijty} * EFkwonsitebatt_{ijty} \qquad (9)$$

Where:

PE_y	= Project emissions in year *y* (tCO_2e)
$NECT_{i,j,s,t,y}$	= Electricity consumed by project chargers supplied from associated infrastructure source *s* net of any kwh EV/charger returned to this same source during time-of-day period *t*, within region *j* serving applicable fleet *i* in project year y (kwh/time period *t*)
$EFkwTODAI_{i,j,s,t,y}$	= Emission factor for the electricity from associated infrastructure source *s* within region *j* consumed by project chargers serving applicable fleet *i* during time-of-day period *t* in year *y* (tCO_2e/kwh)
$LECT_{i,j,t,y}$	= Electricity provided to the grid and/or building from on-site storage battery during time-of-day period *t* within region *j* serving applicable fleet *i* in project year *y* (kwh/year)
$EFkwTODonsitebatt_{i,j,t,y}$	= Emission factor for the electricity from the on-site battery associated infrastructure source *s* during time-of-day period *t* within region *j* consumed by project chargers serving applicable fleet *i* in year *y* (tCO_2e/kwh)

8.3 Leakage

Leakage is not considered an issue under this methodology, and is therefore set at zero.[19]

8.4 Net GHG Emission Reductions and Removals

Net GHG emission reductions must be calculated as follows, including application of a discount factor, D_y, to adjust pro-rata where EV fleet credits have been issued within the project region:

$$ER_y = (BE_y - PE_y - LE_y) * D_y \quad (10)$$

Where:

ER_Y = Net GHG emissions reductions and removals in year *y* (tCO_2e)

BE_Y = Baseline emissions in year *y* (tCO_2e)

PE_y = Project emissions in year *y* (tCO_2e)

LE_y = Leakage in year *y* (tCO_2e)

D_y = Discount factor to be applied in year *y* (%)

Where:

$$D_y = ERC_y/(ERF_y + ERC_y) \quad (11)$$

Where:

D_y = Discount factor to be applied in year *y* (%)

ERC_y = Sum of GHG credits[20] issued by all projects under this methodology (or others which support the introduction of EV charging systems) across this project's applicable fleet *i* categories within this total project region in project year y-1 (tCO_2e)

ERF_y = Sum of GHG credits issued by all projects under methodologies which support the introduction of EV fleets (e.g., CDM AMS.III.C) located within this project's total region

[19] This is consistent with CDM methodology AMS-III.C, which sets leakage at zero. Further analysis of crediting substitution risks between ineligible and eligible EV chargers confirmed substitution risks to be de minimis in the US due to a number of factors. These include: the large distances between public DCFC's and unlikely substitution of public DCFC by public L2 charging; a very low portion of L2s are simultaneously public, accessible (e.g. not restricted workplaces) and excluded from project crediting period under VCS grandfathering rules (when 80-90% of L2 charging takes place in homes). Furthermore, L2 to L2 substitution between eligible and ineligible chargers in this de minimis segment can also be reciprocal reducing leakage still further.

[20] Credits for GHG emission reductions issued under GHG programs such as the American Carbon Registry (ACR) Climate Action Reserve (CAR), Verified Carbon Standard (VCS), or the UNFCCC's Clean Development Mechanism (CDM).

where the applicable fleet *i* categories are the same for both this EV charging system project and projects introducing EV fleets[21], in project year y-1 (tCO_2e)

Where no GHG credits have been issued for projects that introduce EV fleets in the EV charging system project's region, D_y will be 1 (i.e., there is no discount applied).

Where project proponents can demonstrate that the EV charging systems included in the project are comprised of a private or closed charging network (e.g., a private charging network that is in secure garages, or a closed charging network for e-buses owned by a transit agencies where chargers are reserved exclusively for its own public agency fleet), and can demonstrate that relative to this closed or private charging network, no GHG credits have been issued for the introduction of EVs using the network, then D_y will be 1 (i.e., there is no discount applied)[22].

Where GHG credits have been issued for projects that introduce EV fleets for a region larger than the proposed EV charging system project (e.g., a GHG project introducing a fleet of EVs U.S.-wide, while the EV charging system project is confined to one state), then a sensible pro-rata share of the GHG credits issued for the introduction of EV fleets can be estimated for the EV charging system project's region (e.g., using the pro-rata number of EVs on the road in the EV charging system project state compared to the total in the US, using sources such as ZEVFacts.com).

9 MONITORING

Project proponents must follow the monitoring procedures provided below, noting that Sections 9.1., 9.2 and 9.3 below set out parameters and requirements for monitoring projects.

9.1 Data and Parameters Available at Validation

In addition to the parameters given below, estimates for project parameters EF, AFEC, MPG, EV, EVR, $MPG_{a,l,y}$ and ED, which are found in section 9.2, will also be provided as needed at validation.

Data / Parameter:	IR_i
Data unit	Number
Description	Technology improvement factor for applicable fleet i in year y for default value BE calculations.

[21] Therefore, to determine *ERFy*, project proponents must assess projects that introduce EV fleets both based on their location and applicable fleet category to address any potential double counting between GHG credits issued for such projects which introduce fleets of EVs and the GHG credits issued for this EV charging system project.
[22] This is allowed as private and closed charging networks, even if publicly owned, are not subject to the risk that EV fleets with issued certified GHG credits would have access to its charging network, and the EV fleets that do use the network have not issued separate GHG credits of their own. Public charging system operating as open networks would not normally be able to demonstrate such lack of access and therefore must determine if a discount factor must be applied.

Equations	1
Source of data	CDM AMS-III.C which uses the same discount rate in baseline calculations
Value applied	If baselines are calculated using updated BEy parameters for each project year y, $IR_i = 1$ If default values are used for these BEy parameter calculations, For LDV applicable fleets, $IR_i = 1$ For HDV applicable fleets, $IR_i = 0.99$
Justification of choice of data or description of measurement methods and procedures applied	If the baseline is calculated each year using the applicable fleet and conventional fleet statistics in each project year y, then no technology improvement rates need to be applied (since annual accurate data is used each year) $IR_{i,y}$ is therefore set to be 1. IR_i when applied to LDV projects using default values is 1 because default values for MPG factors use individual, specific MPG figures for each fossil fuel vehicle comparable to each EV model in the applicable fleet (see Appendix 1). These MPG figures only change substantially when a fossil fuel model is re-designed/updated by manufacturers which takes place on a 7-10 year cycle: this timeframe is longer than the Verra five year update cycle for parameter updates. IR_i when applied to HDV projects using default values is 0.99 because the defaults values use market-wide, class based comparable MPG factors for default calculations rather than individual, specific MPG figures for the fossil fuel vehicles comparable to each EV model (see Appendix 1) provided that: • This 0.99 improvement rate is applied to each calendar year. • This rate is taken to be 0.99 consistent with the IR default in CDM-III.C. • For project year 1, IR^(y-1) must be 1 (since any number to power 0 is 1). See justification in MPG below.
Purpose of Data	Calculation of baseline emissions
Comments	For LDV projects, the default equivalent MPG are taken from specific comparable vehicles (rather than classes of vehicles) whose MPG are only likely to change with major model upgrades (and thus remain steady for many years).

9.2 Data and Parameters Available at Verification

Data / Parameter:	$EF_{j,f,y}$
Data unit	tCO_2 or CO_2e/gallon
Description	Emission factor for the fossil fuel *f* used by the fossil fuel vehicles deemed comparable to each EV in applicable fleet *i* in year *y*
Equations	1
Source of data	Use values from credible international or national government sources such as, for the US, the EPA emissions factor[23].
Value applied	For LDV projects located in the US and Canada: L1/L2 (BEV and PHEV average) = 0.0088 tCO_2 or 0.0088 tCO_2e per gallon DCFC (BEV average) = 0.0088 tCO_2 or 0.0088 tCO_2e per gallon For HDV projects located in the US: e-buses = 0.0102 tCO_2 or 0.0102 tCO_2e per gallon e-trucks = 0.0102 tCO_2 or 0.0102 tCO_2e per gallon Projects must apply the default value using units (CO_2 or CO_2e) consistent with their project boundary choices, consistent across all project activity sources.
Justification of choice of data or description of measurement methods and procedures applied	International and national government transportation fuel emission rates have been widely established and peer reviewed. US & Canada default values calculated in Appendix 1. Note that if countries provide EF fuel emission factors using slightly different units such as CO_2 per liter simple conversions must be made during validation One common conversation from CO_2 per liter to CO_2 per gallon is given below: CO2 per gallon = CO2 per liter * 3.785 Based upon conversion factors of: 1 gall = 3.785 liters
Purpose of Data	Calculation of baseline emissions
Comments	Calculated annually, based on the fuels consumed by the fossil fuel vehicles deemed comparable to the EV models on the road each year in the applicable fleet, unless default values for baseline calculations for LDVs and/or HDVs are used.

[23] https://www.epa.gov/sites/production/files/2015-11/documents/emission-factors_nov_2015.pdf

Data / Parameter:	$AFEC_{iy}$
Data unit	kwh/100 miles
Description	Weighted average electricity consumption per 100 miles rating for EVs in applicable fleet *i* in project year *y*
Equations	1 and 2
Source of data	Calculated in Equation 2
Value applied	For LDV projects located in the US: L1/L2 (BEV and PHEV average) = 33.32 DCFC (BEV average) = 31.88 For HDV projects located in the US: e-buses = 300 e-trucks = 140 For LDV projects located in Canada: L1/L2 (BEV and PHEV average) = 35.44 DCFC (BEV average) = 33.00
Justification of choice of data or description of measurement methods and procedures applied	Analysis calculations can be found in Appendix 1. Changes in the value of $AFEC_{iy}$ are very gradual over time. Default values for $AFEC_{iy}$ must be updated each 5 years alongside the activity method updates US & Canada default values calculated in Appendix 1.
Purpose of Data	Calculation of baseline emissions
Comments	Calculations for AFEC for open networks (where the exact EV models charging are not known) must be established using such data sources which must be compiled on a national basis (that is, for example, the number of BEV's of each model on the road in the US for open DCFC networks). Calculations for AFEC for closed networks (e.g. where the composition and operating characteristics of both the applicable and comparable fleets are known and documented, such as with transit agency e-bus fleets) may be made using the specific composition of these fleets (that is, for example, EVR must be the number of e-buses on the road for that particular transit agency fleet). For both open and closed networks, the individual EV model's EV ratings (kwh/100 miles) must be used as applicable to the government rating agencies from which they have been sourced, (e.g. nationally for US; supra-nationally for EU), including in the periodic update of default values.

	Note again that if EVs are rated using slightly different variables such as kwh/100 km in Europe simple conversions must be made during validation. One common conversation from kwh/100km to kwh/100 miles is given below: kwh per 100 miles = kwh per 100km * 0.6215 Based upon conversion factors of: 100 km = 62.15 miles

Data / Parameter:	MPG_{iy}
Data unit	miles per gallon
Description	Weighted average miles per gallon rating for fossil fuel vehicles deemed comparable to each EV in applicable fleet *i* in project year *y*
Equations	1 and 3
Source of data	Derived in Equation 3
Value applied	<u>For LDV projects located in the US:</u> L1/L2 (BEV and PHEV average) = 29.18 DCFC (BEV average) = 29.10 <u>For HDV projects located in the US:</u> e-buses = 4.34 e-trucks = 8.60 <u>For LDV projects located in Canada:</u> L1/L2 (BEV and PHEV average) = 29.65 DCFC (BEV average) = 27.71
Justification of choice of data or description of measurement methods and procedures applied	US & Canada default values calculated in Appendix 1 For LDV projects, changes in the value of MPG_{iy} are very gradual over time given that a particular EV model's comparable fossil fuel vehicle rating must remain relatively steady for many years until the vehicle is significantly re-engineered. Thus for LDV projects, the default equivalent MPG's are taken from specific comparable vehicles (rather than classes of vehicles) whose MPG's are only likely to change with major model upgrades (and thus remain static for many years). For HDV projects, the class average MPG has been taken as the source data (see Appendix 1) so the discount rate IR_i of 0.99 must still apply. Default values for MPG_{iy} must be updated each 5 years with the activity method updates.

Purpose of Data	Calculation of baseline emissions
Comments	Consistent with guidance provided in AFEC above, weighted average is calculated for project year y based upon the number of EVs of each EV model type a in applicable fleet i on the road in project year *y* (EVR_{aiy}) combined with the mile per gallon ratings for each of these EV model's comparable fossil fuel vehicle ($MPG_{a,I,y}$). Calculations for comparable fleet's average MPG for open networks (where the exact EV models charging are not known) must be established using such data sources which must be compiled on a national basis (that is, for example, the number of BEV's of each model on the road in the US for open DCFC networks). Calculations for these fleet's MPG for closed networks (e.g. where the composition and operating characteristics of both the applicable and comparable fleets are known and documented, such as with transit agency e-bus fleets) may be made using the specific composition of these fleets (that is, for example, EVR must be the number of e-buses on the road for that particular transit agency fleet). For HDV closed networks, if the composition and operating characteristics of both the applicable and comparable fleets are known and documented (e.g. for transit agency EV charging infrastructure where the MPG's for the agency's own baseline bus operations can be established as the agency's comparable fleet of fossil fuel buses) using any of the CDM AMS-III.C Approach 1, Options 1 – 5, paragraphs 32 - 37. For both open and closed networks, the individual fossil fuel model's MPG ratings must be used as applicable to the government rating agencies from which they have been sourced (e.g., nationally for US; supra-nationally for EU), including in the periodic update of default values. MPG_{iy} is calculated annually unless the default values for baseline calculations for LDVs and/or HDVs is used following Equation 4, which employs the default value $DMPG_{iy}$. US & Canada default values calculated in Appendix 1. If standard emission values are provided using different parameters (such as CO_2/km as fossil fuel vehicle emission factors in Europe) conversions to given variable units will be made. One common conversation from liters per 100 km to miles per gallon is given below:

	MPG = 235.24 / liters per 100 km Based upon conversion factors of: 1 gall = 3.785 liters 100 km = 62.15 miles

Data / Parameter:	EV_{aiy}
Data unit	kwh/100 miles
Description	Electricity kwh consumption per 100 miles rating for EV model a within applicable fleet *i* in project year *y*
Equations	2
Source of data	Use values from credible national governmental sources such as the ratings for the US provided by US DoE Fuel Economy program[24].
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	National, governmental ratings provide independent third party public source.
Purpose of Data	Calculation of baseline emissions
Comments	See guidance for AFEC above. For both open and closed networks, the EV_{aiy} ratings must be used as applicable to the government rating agencies from which they have been sourced, e.g. nationally for US; supra-nationally for EU.

Data / Parameter:	EVR_{aiy}
Data unit	Cumulative number of EVs
Description	Total number of EV model *a* within applicable fleet *i* on the road by project year *y*
Equations	2 and 3
Source of data	Use values from credible national governmental sources such as the statistics provided for the US provided by the Argonne National Laboratory's monthly email updates[25]

[24] https://www.fueleconomy.gov/feg/evsbs.shtml
[25] Such as the *U.S. E-Drive vehicle monthly updates_February 2017* provided via email by ANL. The main ANL web link is found here including the email address for the database manager: https://www.anl.gov/energy-systems/project/light-duty-electric-drive-vehicles-monthly-sales-updates
[25] https://www.fueleconomy.gov/feg/pdfs/guides/FEG2016.pdf

	Closed networks may also use the number of EV's on the road using their known composition and operating characteristics of the applicable fleets they serve.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	Argonne National Laboratory is an independent, trusted government source of EV data for the US market.
Purpose of Data	Calculation of baseline emissions
Comments	This value is calculated for project year y based upon the cumulative number of EVs of each EV model type *a* in applicable fleet *i* on the road by project year *y*, consistent with AFEC guidance above. In the USA, statistics for the number of EVs on the road by model type is available from several sources including Argonne National Laboratory, in their monthly emails[26], which draws upon data from hybridcars.com[27].

Data / Parameter:	$MPG_{a,I,y}$
Data unit	miles/gallon
Description	Mile per gallon rating for fossil fuel vehicle model(s) deemed comparable to EV model a from applicable fleet *i* in project year *y*
Equations	3
Source of data	See guidance for MPG_{iy} above. Use values from credible national government sources such as the US rating found in the *2016 Fuel Economy Guide*[28] For both open and closed networks, the $MPG_{a,I,y}$ ratings must be used as applicable to the government rating agencies from which they have been sourced (e.g., nationally for US; supra-nationally for EU.)
Value applied	N/A

[26] See U.S. E-Drive vehicle monthly updates_February 2017 provided via email by ANL. https://www.anl.gov/energy-systems/project/light-duty-electric-drive-vehicles-monthly-sales-updates
[27] Argonne National Lab's (ANL) monthly emails uses data sourced from the hybridcars.com web site: http://www.hybridcars.com/december-2016-dashboard/ The main ANL web link is found here including the email address for the database manager: https://www.anl.gov/energy-systems/project/light-duty-electric-drive-vehicles-monthly-sales-updates
[28] https://www.fueleconomy.gov/feg/pdfs/guides/FEG2016.pdf

Justification of choice of data or description of measurement methods and procedures applied	National governmental ratings such as those found in the US Fuel Economy Guides for the US market are independent, trusted government sources of fuel consumption ratings.
Purpose of Data	Calculation of baseline emissions
Comments	If standard emission values are provided using parameters which already incorporate fuel emission factors such as CO_2/km ratings for fossil fuel vehicle emission factors in Europe then conversions to the appropriate combination of variables must be made to establish equivalence to the parameters in these equations. For example, in Europe, fossil fuel vehicle are rated in terms of CO_2 per km (given here as EFEU). Therefore, if the EV ratings are still given as kwh per 100 miles, then such a conversion would be: CO_2 per mile = $EF_{j,f,y}$ / $MPG_{a,l,y}$ = EFEU / 0.62.

Data / Parameter:	$ED_{i,y}$
Data unit	Kwh/year
Description	Quantity of electricity delivered to EV's by project chargers serving applicable fleet i in project year y
Equations	1
Source of data	kwh delivered to EV's for project charging network using systems' actual or estimated kwh values, as below. Note that for L2 chargers, the electricity delivered, ED, will be considered the same as electricity consumed by the chargers EC since L2's are highly efficient chargers with de minimis losses due to their own power consumption. (i.e. ED = EC) For DCFC, baseline emission calculations must use ED which must be based upon the kwh delivered to the EV's which is what the chargers' own internal smart DCFC's meter measure. (By contrast, for project emissions measurements which are based on the electricity consumed by the DCFC (where efficiency losses can be more material) kwh data can be sourced either A) from this ED provided that a DCFC efficiency factor is applied or B) from kwh data metered on the grid-side of the charging system and any associated AI. See EC, ECTOD, NEC and NECT parameter boxes below for PE applications.)
Value applied	Measured value based on kwh delivered by charging systems in year y

Description of measurement methods and procedures to be applied	The kwh delivered by the charging systems for each applicable fleet i must be sourced using the following hierarchy, where projects must apply first those listed highest on the list: 1) Actual kwh sourced using smart charger measurement systems or (for L2's only) on-site grid electricity meters 2) Estimates for a project's dumb network charger segments based upon the portions of the project which has available such smart network project averages or utility-style project user survey data applicable to these same segments (e.g. for each applicable fleet across comparable segments (public, workplace, residential etc)) 3) Investments to upgrade chargers to provide actual "smart" data results by installing technologies which effectively retrofit metering[29] 4) Use of reasonable regionally applicable pilot project data (such as local utility project results) for non-metered project chargers that don't have smart actual measurements when this pilot data reasonably corresponds to comparable utilization rates to those in the project 5) In the US, use of the Department of Energy/Idaho National Laboratory's (DoE/INL) EV Project data[30] to apply average kwh per charging event data which is provided across a) different settings (public, residential, non-private residential) and b) for each US state For #2 and 4, validator reviews must consider whether projects are applying "smart"/utility/pilot project data using an appropriate project segmentation basis, so that there is a reasonably comparable basis upon which chargers operate in the "dumb" and "smart" segments. This comparability provides a reasonable basis upon which to apply the representative smart segment averages to the corresponding dumb segments of the project. Use calibrated electricity meters/smart charging system measurement systems. Calibration must be conducted according to the equipment manufacturer's specifications.
Frequency of monitoring/recording	Measured actual data must be monitored and recorded on at least an annual basis; monitoring periods for metered data can be consistent with utility reports. Estimated consumption can be

[29] For example, EMotorWerks Juicebox
[30] https://avt.inl.gov/project-type/ev-project

	made on annual basis from sources which monitor using measured/actual or metered sources per the hierarchy above.
QA/QC procedures to be applied	The consistency of metered electricity consumption should be cross-checked with receipts from electricity purchases where applicable
Purpose of Data	Calculation of baseline emissions
Calculation method:	
Comments	N/A

Data / Parameter:	$EC_{i,y}$
Data unit	Kwh/year
Description	Quantity of electricity consumed by project chargers serving applicable fleet *i* in project year *y*
Equations	4
Source of data	kwh consumption for project charging network using systems' actual or estimated kwh values, as below Note that for L2 chargers, the electricity consumed EC will be considered the same as electricity delivered to the EV's by the chargers, ED, since L2's are highly efficient chargers with de minimis losses due to their own power consumption. (i.e. ED = EC) For DCFC, EC must be based upon the kwh consumed by the charging system (since efficiency losses can be more material for DCFC's). DCFC EC data can therefore either be sourced via: A) ED, the chargers' own internal smart DCFC's meter data, provided that a DCFC efficiency factor of 92.3% is applied to the smart charger metered data[31] or B) meters which are on the grid-side of the DCFC units/AI If a project can demonstrate to validators a more accurate efficiency factor for their particular DCFC systems (for example due to improvements in DCFC technology efficiencies over time) this updated accurate efficiency factor may be substituted for the 92.3% default efficiency value.
Value applied	Measured value based on kwh consumed by charging systems in year y For DCFC, using approach A, $EC_{i,y} = ED_{i,y}/0.923$

[31] The 92.3% DCFC efficiency factor is derived from Idaho National Lab powerpoint findings as reviewed with the VVB.

Description of measurement methods and procedures to be applied	The kwh consumed by the charging systems for each applicable fleet i must be sourced using the following hierarchy, where projects must apply first those listed highest on the list: 1) Actual kwh consumed using smart charger measurement systems or on-site electricity meters 2) Estimates for a project's dumb network charger segments based upon the portions of the project which has available such smart network project averages or utility-style project user survey data applicable to these same segments (e.g. for each applicable fleet across comparable segments (public, workplace, residential etc)) 3) Investments to upgrade chargers to provide actual "smart" data results by installing technologies which effectively retrofit metering[32] 4) Use of reasonable regionally applicable pilot project data (such as local utility project results) for non-metered project chargers that don't have smart actual measurements when this pilot data reasonably corresponds to comparable utilization rates to those in the project 5) In the US, use of the Department of Energy/Idaho National Laboratory's (DoE/INL) EV Project data[33] to apply average kwh per charging event data which is provided across a) different settings (public, residential, non-private residential) and b) for each US state For #7 and 9, validator reviews must consider whether projects are applying "smart"/utility/pilot project data using an appropriate project segmentation basis, so that there is a reasonably comparable basis upon which chargers operate in the "dumb" and "smart" segments. This comparability provides a reasonable basis upon which to apply the representative smart segment averages to the corresponding dumb segments of the project. Use calibrated electricity meters/smart charging system measurement systems. Calibration must be conducted according to the equipment manufacturer's specifications.
Frequency of monitoring/recording	Measured actual data must be monitored and recorded on at least an annual basis; monitoring periods for metered data can be consistent with utility reports. Estimated consumption can be made on annual basis from sources which monitoring using measured/actual or metered sources.

[32] For example, EMotorWerks Juicebox
[33] https://avt.inl.gov/project-type/ev-project

QA/QC procedures to be applied	The consistency of metered electricity consumption should be cross-checked with receipts from electricity purchases where applicable
Purpose of Data	Calculation of baseline and project emissions
Calculation method:	
Comments	N/A

Data / Parameter	$EFkw_{i,j,y}$
Data unit	tCO_2e/kwh
Description	Emission factor for the electricity sourced from region *j* consumed by project chargers serving applicable fleet *i* in year *y*
Equations	4
Source of data	Use credible government data sources such as, for the US, the regional eGRID emission factors published by EPA[34]
Description of measurement methods and procedures to be applied	The emission factor must be consistent with the region j from which electricity is sourced (e.g. for the US with the utility's eGRID region[35]). Published utility specific emission factors are allowed for the kwh consumed from that source consistent with VCS practices which allow well documented more local electricity sources' GHG emission factors to be applied. Average emission factors (not marginal) must be used Grid-sourced and dedicated renewable kwh is treated as having zero tCO2e/kwh. Biogenic sources used on-site to generate electricity are considered dedicated renewables. Other on-site biofuels used to generate electricity must apply and justify their own emission factors for the biofuel used, such as those referenced in the same EPA source from which the other fuel emission default factors (EF) were derived[36].
Frequency of monitoring/recording	Annual updates from these published sources
QA/QC procedures to be applied	
Purpose of data	Calculation of project emissions

[34] https://www.epa.gov/energy/emissions-generation-resource-integrated-database-egrid
[35] https://www.epa.gov/sites/production/files/2017-02/documents/egrid2014_summarytables_v2.pdf
[36] https://www.epa.gov/sites/production/files/2015-07/documents/emission-factors_2014.pdf

Calculation method:	Look up value
Comments:	Region *j* represents any region from which electricity is sourced, each of which must have a well-documented emissions factor for the electricity provided. For US projects, electricity emissions must be estimated using the EPA regional eGRID emission rates, unless other more accurate local/regional sources are available (e.g. from utilities directly serving the charging network).

Data / Parameter	$ECTOD_{i,j,t,y}$
Data unit	Kwh/time period t
Description	Quantity of electricity consumed by project chargers sourced from region j serving applicable fleet i during time of day period t in project year y
Equations	5
Source of data	kwh consumption for project charging network using systems' actual values provided these are generated using time-of-day metering The same guidance provided for $EC_{i,y}$ relative to the sources of data for L2 and DCFC apply here. So L2 data can be sourced from kwh measured as delivered to EV's or consumed by the chargers since efficiency losses are de minimis. And DCFC data may either be sourced via A) DCFC's own internal smart meter systems, provided that a DCFC efficiency factor of 92.3% is applied; or B) meters which are on the grid-side of the DCFC units/AI. Thus again for DCFC, using approach A, the value applied would be $ECTOD_{i,j,t,y}/0.923$ If a project can demonstrate to validators a more accurate efficiency factor for their particular DCFC systems (for example due to improvements in DCFC technology efficiencies over time) this updated accurate efficiency factor may be substituted for the 92.3% default efficiency value.
Description of measurement methods and procedures to be applied	The kwh supplied by the charging systems applying time of day calculations in equation 6 must be sourced as follows: 1. Using actual time-of-day kwh measurements using smart charger measurement systems or on-site electricity meters, capable of recording/monitoring kwh consumption on at minimum an hourly basis

	3. Investments to upgrade chargers to provide such time-of-day actual data results are permitted provided they supply comparable hourly reporting Electricity meters' calibration must be conducted according to the equipment manufacturer's specifications.
Frequency of monitoring/recording	Data must be monitored continuously and recorded on at least an hourly basis.
QA/QC procedures to be applied	The consistency of metered electricity generation should be cross-checked with receipts from electricity purchases where applicable
Purpose of data	Calculation of project emissions
Calculation method:	
Comments:	The sum of all such time-of-day time periods, t, must equal 24 in any given full day within the project (i.e. there are no time periods in which electricity is provided but not accounted for within PEy). This is applicable only if PE emissions are to be calculated on a time-of-day basis.

Data / Parameter	$EFkwTOD_{j,j,t,y}$
Data unit	tCO_2e/kwh
Description	Emission factor for the electricity sourced from region j consumed by project chargers serving applicable fleet i during time of day period t in year y
Equations	5
Source of data	Use credible governmental or regional utility data sources such as, for the US, those published in the US by ISO's which rely upon utilities' hourly fuel consumption figures (e.g. see PJM publications[37]) Time of day estimates for electricity emission factors, $EFkw_{i,j,t,y}$ must be drawn from credible, applicable sources (e.g. the regional ISO or applicable utility generation sources).
Description of measurement methods and procedures to be applied	If $EFkwTOD_{j,j,y}$ has already been published by utilities in region j on an hourly basis, then these figures must be used. Since hourly EFkwTOD publications may not readily be available, if in region j utilities or ISOs are publishing time of day emission factors on a basis other than hourly, then projects may use this other basis provided it is accepted by validators as reasonable (for

[37] http://www.monitoringanalytics.com/data/marginal_fuel.shtml

	example PJM publishes on-peak and off-peak emission factors) in order to accommodate ISO/utility gradual improvements in best practices for time of day emission factor reporting[38]. If in region j, the ISO provides fuel consumption data on an hourly basis, $EFkwTOD_{j,j,y}$ may be estimated on a weighted average basis using equation 6 Grid-sourced and dedicated renewable kwh is treated as having zero tCO2e/kwh Biogenic sources used on-site to generate electricity are considered dedicated renewables. Other on-site biofuels used to generate electricity must apply and justify their own emission factors for the biofuel used, such as those referenced in the same EPA source from which the other fuel emission default factors (EF) were derived[39].
Frequency of monitoring/recording	Source data (for emission factor $EFkwTOD_{j,j,y}$) must be monitored continuously and recorded on at least an hourly or prevailing best practice basis.
QA/QC procedures to be applied	
Purpose of data	Calculation of project emissions
Calculation method:	If $EFkwTOD_{j,j,y}$ is estimated using hourly fuel consumption reports (e.g. from an ISO), the weighted average calculations are given in equation 6
Comments:	The sum of all such time-of-day time periods, t, must equal 24 in any given full day within the project (i.e. there are no time periods in which electricity is provided but not accounted for within PEy). This is applicable only if PE emissions are to be calculated on a time-of-day basis

Data / Parameter	$EFkwF_{j,j,t,f,\ y}$
Data unit	tCO_2e/kwh
Description	Emission factor applicable for the fuel type f used to generate the kwh during time of day period t sourced from region j consumed by project chargers serving applicable fleet i in year y
Equations	6

[38] There are no utility/ISO EFkw hourly published rates yet available (only fuel consumption rates) but as the PJM on-peak/off-peak publications indicate such TOD rates will become more accessible over time
[39] https://www.epa.gov/sites/production/files/2015-07/documents/emission-factors_2014.pdf

Source of data	Use credible governmental or regional utility data sources such as, for the US, those published in the US by ISO's which rely upon utilities' hourly fuel consumption figures (e.g. see PJM publications[40])
Description of measurement methods and procedures to be applied	If in region j, the ISO provides fuel consumption data on an hourly basis, $EFkwF_{j,j,t,f,y}$ may be estimated on a weighted average basis using equation 6 as follows: • Projects must combine the hourly fuel consumption figures (typically given as the percentage of each type of fuel consumed that hour (50% coal, 50% natural gas)) with the emission factors for these same fuels to create a weighted average emission rate for each hourly period. • Emission rates for each fuel must be drawn from the same (e.g. the ISO) or consistent publication sources for region j (noting that these need not be generated on an hourly basis but must be updated on at least an annual basis)
Frequency of monitoring/recording	Each fuel's emission rate need not be generated on an hourly basis but averages must be generated on at least an annual basis.
QA/QC procedures to be applied	
Purpose of data	Calculation of project emissions
Calculation method:	
Comments:	Applicable only if PE emissions are to be calculated on a time-of-day basis using utility/ISO hourly fuel consumption inputs

Data / Parameter	$F\%_{ijtfy}$
Data unit	%
Description	Percentage of fuel type f used to generate the kwh DURING EACH time of day period t, sourced from region j and consumed by project chargers serving applicable fleet I in year y
Equations	6
Source of data	Use credible governmental or regional utility data sources such as, for the US, those published in the US by ISO's which rely upon utilities' hourly fuel consumption figures (e.g. see PJM publications[41])

[40] http://www.monitoringanalytics.com/data/marginal_fuel.shtml
[41] http://www.monitoringanalytics.com/data/marginal_fuel.shtml

Description of measurement methods and procedures to be applied	The hourly fuel consumption figures are typically given as the percentage of each type of fuel consumed that hour (50% coal, 50% natural gas)).
Frequency of monitoring/recording	This fuel sourced parameter data must be monitored and recorded on at least an hourly basis. Since the emission factors for each fuel type f need not be generated on an hourly but can be supplied on an annual basis, the percentage of each fuel type f used to generate the kwh during each time period will be supplied for each such time period.
QA/QC procedures to be applied	Typically a look up value
Purpose of data	Calculation of project emissions
Calculation method:	
Comments:	Applicable only if PE emissions are to be calculated on a time-of-day basis using utility/ISO hourly fuel consumption inputs

Data / Parameter	$NEC_{i,j,s,y}$
Data unit	kwh/year
Description	Electricity consumed by project chargers supplied from associated infrastructure source s net of any kwh EV/charger returned to this same source within region j serving applicable fleet i in project year y
Equations	7
Source of data	Net kwh consumption/generation for project chargers must be secured for each associated infrastructure source (whether derived from the grid, dedicated renewables or the on-site battery) as actual net kwh values using chargers' adequate metering systems The same core guidance provided for $EC_{i,y}$ relative to the sources of data for L2 and DCFC apply here. So L2 data can be sourced from kwh measured as delivered to EV's by the charger meter or as the kwh consumed by the chargers from a grid-based source since losses are de minimis. And DCFC data may either be sourced via A) DCFC's own internal smart meter systems capable of differentiating the net kwh delivered to the EV's from each source s, provided that a DCFC efficiency factor of 92.3% is applied; or B) meters which are on the grid-side of the DCFC units/AI for each source s.

	Thus again for DCFC, using approach A, the value applied would be $NEC_{i,j,s,y}$ /0.923 If project can demonstrate to validators a more accurate efficiency factor for their particular DCFC systems (for example due to improvements in DCFC technology efficiencies over time) this updated accurate efficiency factor may be substituted for the 92.3% default efficiency value.
Description of measurement methods and procedures to be applied	Projects must track the net kwh consumption/generation for charging systems from across all potential associated infrastructure sources, s, (whether grid, dedicated renewable sources, on-site battery), net of kwh supplied back from the EV battery to such sources, using the charger's metering system to track such net kwh calculations. To apply equation 7, such net kwh values must be sourced as follows: 1) Using actual kwh consumption and generation measurements using on-site or smart chargers' metering systems, capable of recording/monitoring kwh both consumed and generated on at minimum a yearly basis 2) Investments to upgrade chargers to provide such net metered actual data results are permitted provided they supply comparable reporting Associated infrastructure sources, s, for which NEC is calculated include: • grid-connected electricity from region j • and/or dedicated renewable energy generated on-site (including RE sourced from direct transmission lines) • and/or the EV vehicle's on-board battery Each of the grid and renewables sources, s, must have a well-documented emissions factor for the electricity sourced and/or dispatched Project metering systems' calibration must be conducted according to the equipment manufacturer's specifications. Projects must incorporate adequate metering systems when applying Eq 7. Guidance for the design/application of such metering systems is provided in Appendix 2.
Frequency of monitoring/recording	Measured actual data must be monitored and recorded on at least an annual basis. Monitoring periods for metered net data can be consistent with reports which the charging systems' metering system provides.

QA/QC procedures to be applied	The consistency of net metered electricity generation should be cross-checked with receipts and invoices from electricity purchases and sales where applicable
Purpose of data	Calculation of project emissions
Calculation method:	
Comments:	The charging system's metering system must adequately and accurately measure and traces such electricity deliveries and receipts from these associated infrastructure sources, (including for example electricity sourced from/returned to the grid, on-site/dedicated renewables, on-site batteries, EV batteries). Applicable only if PE emissions are to be calculated on a net metered basis integrating multiple associated infrastructure sources, s. Note: time of day, hourly monitoring of EV charging/associated infrastructure deliveries and receipts is not a necessary requirement to apply Equation 7. For combined associated infrastructure metering and time of day PE estimates, see parameters for equation 9.

Data / Parameter	$EFkwAI_{i,,j,s,y}$
Data unit	(tCO_2e/kwh)
Description	Emission factor for the net electricity from each associated infrastructure source s within region j consumed by project chargers serving applicable fleet i in year y
Equations	7
Source of data	Each of associated infrastructure source, s, must have a well-documented emissions factor for the electricity it supplies and/or dispatches as follows: • Grid-connected electricity from region j must follow the same procedures as for parameter $EFkw_{i,j,y}$ in Equation 4 (see above) • Dedicated renewable energy generated on-site, including renewable energy sourced via direct transmission lines, must set emission factors at zero • On-site storage batteries must assume the weighted average emission factor based upon the proportionate net consumption of grid and dedicated renewable energy at the charging system (see equation 8)

Description of measurement methods and procedures to be applied	For grid-connected electricity, see procedures for parameter $EFkw_{i,j,y}$ in Equation 4 For dedicated renewables, emission factors are set at zero. For on-site storage batteries, the calculations are given in equation 8. Projects must incorporate adequate metering systems when applying Eq 7 and 8. Guidance for the design/application of such metering systems is provided in Appendix 2.
Frequency of monitoring/recording	Annual, per procedures for parameter $EFkw_{i,j,y}$ in Equation 4
QA/QC procedures to be applied	
Purpose of data	Calculation of project emissions
Calculation method:	For on-site batteries see equation 8
Comments:	Applicable only if PE emissions are to be calculated on a net metered basis integrating multiple associated infrastructure sources, s. Note: time of day, hourly monitoring of EV charging/associated infrastructure deliveries and receipts is not a necessary requirement to apply Equation 7. For combined associated infrastructure metering and time of day PE estimates, see parameters for equation 9.

Data / Parameter	$LEC_{j,,j,y}$
Data unit	kwh/year
Description	Electricity provided to the grid and/or building from on-site storage battery within region j serving applicable fleet i in project year y (kwh/year)
Equations	7
Source of data	From on-site battery/charging system's adequate measurement systems
Description of measurement methods and procedures to be applied	LEC arises if on-site batteries provide kwh back to the grid or local building (for example if used as back up generators/sources of power). These kwh are not supplied to the EV charging system

	and do not result in EV miles drive and so are deducted out in Eq 7. Projects must incorporate adequate metering systems when applying Eq 7. Guidance for the design/application of such metering systems is provided in Appendix 2. Project metering systems' calibration must be conducted according to the equipment manufacturer's specifications.
Frequency of monitoring/recording	Measured actual data must be monitored and recorded on at least an annual basis.
QA/QC procedures to be applied	The consistency of such kwh should be cross-checked with other information sources where applicable
Purpose of data	Calculation of project emissions
Calculation method:	
Comments:	Applicable only if PE emissions are to be calculated on a net metered basis integrating multiple associated infrastructure sources, s. Note: time of day, hourly monitoring of EV charging/associated infrastructure deliveries and receipts is not a necessary requirement to apply Equation 7. For combined associated infrastructure metering and time of day PE estimates, see parameters for equation 9.

Data / Parameter	$EFkwonsitebatt_{i,j,s,y}$
Data unit	(tCO_2e/kwh)
Description	Emission factor for the electricity from the on-site batteries as associated infrastructure sources s within region j consumed by project chargers serving applicable fleet i in year y
Equations	8
Source of data	See data sources for Equation 8 variables below
Description of measurement methods and procedures to be applied	The emission factors for the on-site battery as an associated infrastructure source are calculated using the net weighted average of the grid and on-site renewable emission factors given using equation 8 • On-site storage batteries must assume the weighted average emission factor based upon the proportionate net consumption of grid and dedicated renewable energy at the charging system (using equation 8)

	Projects must incorporate adequate metering systems when applying Eq 8. Guidance for the design/application of such metering systems is provided in Appendix 2.
Frequency of monitoring/recording	Annual
QA/QC procedures to be applied	As for equation 8 variables below
Purpose of data	Calculation of project emissions
Calculation method:	
Comments:	Applicable only if PE emissions are to be calculated on a metered basis integrating multiple associated infrastructure sources, s.

Data / Parameter	$ECB_{i,j,z,y}$
Data unit	kwh/year
Description	Electricity consumed by on-site battery from associated infrastructure sources z, which comprise only the grid-connected and dedicated renewable sources, within region j serving applicable fleet i in project year y
Equations	8
Source of data	As for $NEC_{i,j,s,y}$ in equation 7
Description of measurement methods and procedures to be applied	As for $NEC_{i,j,s,y}$ in equation 7 Projects must incorporate adequate metering systems when applying Eq 8. Guidance for the design/application of such metering systems is provided in Appendix 2. In particular, metering systems must need to measure the kwh delivered to the onsite battery from grid and/or renewable sources as distinct from those delivered directly to the EV charger from the grid and/or dedicated renewable sources
Frequency of monitoring/recording	As for $NEC_{i,j,s,y}$ in equation 7
QA/QC procedures to be applied	
Purpose of data	Calculation of project emissions
Calculation method:	As for $NEC_{i,j,s,y}$ in equation 7
Comments:	Applicable only if PE emissions are to be calculated on a metered basis integrating multiple associated infrastructure sources, s,

	when these sources are grid-connected electricity and dedicated renewable energy.

Data / Parameter	$EFkwAI\text{-}Z_{j,,j,z,y}$
Data unit	(tCO_2e/kwh)
Description	Emission factor for the electricity from the associated infrastructure sources, z, which comprise only the grid-connected and dedicated renewable sources, within region j consumed by on site battery serving applicable fleet i in year y
Equations	8
Source of data	As for $EFkwAI_{j,,j,s,y}$ for grid connected and renewable energy in equation 7
Description of measurement methods and procedures to be applied	As for $EFkwAI_{j,,j,s,y}$ for grid connected and renewable energy in equation 7 Projects must incorporate adequate metering systems when applying Eq 8. Guidance for the design/application of such metering systems is provided in Appendix 2.
Frequency of monitoring/recording	As for $EFkwAI_{j,,j,s,y}$ for grid connected and renewable energy in equation 7
QA/QC procedures to be applied	
Purpose of data	Calculation of project emissions
Calculation method:	As for $EFkwAI_{j,,j,s,y}$ for grid connected and renewable energy in equation 7
Comments:	Applicable only if PE emissions are to be calculated on a metered basis integrating multiple associated infrastructure sources, s, when these sources are grid-connected electricity and dedicated renewable energy.

Data / Parameter	$NECT_{i,j,s,t,y}$
Data unit	Kwh/time period t
Description	Electricity consumed by project chargers supplied from associated infrastructure source s net of any kwh EV/charger returned to this same source during time-of-day period t, within region j serving applicable fleet i in project year y
Equations	9

Source of data	Net electricity consumed by project chargers during time-of-day period t from associated infrastructure sources s, within region j serving applicable fleet i in project year y The same core guidance provided for $EC_{i,y}$ relative to the sources of data for L2 and DCFC apply here. So L2 data can be sourced from kwh measured as delivered to EV's by the charger meter or as the kwh consumed by the chargers from a grid-based source since losses are de minimis. And DCFC data may either be sourced via A) DCFC's own internal smart meter systems capable of differentiating the net kwh delivered to the EV's from each source s during time period t, provided that a DCFC efficiency factor of 92.3% is applied; or B) meters which are on the grid-side of the DCFC units/AI for each source s and time period t. Thus again for DCFC, using approach A, the value applied would be $NECT_{i,j,s,t,y}$ /0.923 If a project can demonstrate to validators a more accurate efficiency factor for their particular DCFC systems (for example due to improvements in DCFC technology efficiencies over time) this updated accurate efficiency factor may be substituted for the 92.3% default efficiency value.
Description of measurement methods and procedures to be applied	Follow those for parameters $EC_{i,j,t,y}$ in equation 5 and $NEC_{i,j,s,y}$ in equation 7 Projects must incorporate adequate metering systems when applying Eq 9. Guidance for the design/application of such metering systems, considered as applied to each time period t, is provided in Appendix 2. In addition, for time of day applications of associated infrastructure calculations pertaining to the NECT for an on-site battery's kwh delivered to the EV charger, metering must be applied "upstream", on the grid-side of the on-site battery. That is for the calculation of NECT for an on-site battery, Eq 9 must, using upstream meters, calculate the kwh delivered to EV chargers via the on-site battery from grid and/or dedicated renewable sources during the time of day period t taking into account *when* these kwh are actually delivered *to the on-site battery* (not when delivered from this battery to the EV charger) since the GHG impacts for these kwh arise on the grid system when they are first delivered into this associated infrastructure system (that is are delivered to the on site battery) For these applications, kwh supplied by the EV to the on-site battery can be set aside (since they return to the EV at a later

	date) unless, during a given time period t, the LEC less the kwh received by the on site battery from grid and renewable sources less the on-site battery's stored kwh is greater than zero – that is LEC is so large that it must have drawn upon the kwh delivered to the on-site battery from the EV In the context of these NECT calculations for the on-site battery, it should be noted that the kwh supplied from the grid to the EV charging system directly – and those kwh supplied by the EV back to the grid – during any time period t are still considered separately in the calculation of NECT for the grid.
Frequency of monitoring/recording	Follow those for parameters $EC_{i,j,t,y}$ in equation 5 and $NEC_{i,j,s,y}$ in equation 7
QA/QC procedures to be applied	Follow those for parameters $EC_{i,j,t,y}$ in equation 5 and $NEC_{i,j,s,y}$ in equation 7
Purpose of data	Calculation of project emissions
Calculation method:	
Comments:	Follow those for parameters $EC_{i,j,t,y}$ in equation 5 and $NEC_{i,j,s,y}$ in equation 7 Applicable only if PE emissions are to be calculated on a time-of-day basis when also incorporating charging systems' associated infrastructure sources on a metered basis.

Data / Parameter	$EFkwTOD\text{-}AI_{i,j,s,t,y}$
Data unit	tCO_2e/kwh
Description	Emission factor for the electricity from associated infrastructure source s within region j consumed by project chargers serving applicable fleet i during time-of-day period t in year y
Equations	9
Source of data	Follow those for parameters $EFkwTOD_{j,,j,t,y}$ in equation 5 and $EFkwAI_{j,,j,s,y}$ in equation 7
Description of measurement methods and procedures to be applied	Follow those for parameters $EFkwTOD_{j,,j,t,y}$ in equation 5 and $EFkwAI_{j,,j,s,y}$ in equation 7 Projects must incorporate adequate metering systems when applying Eq 9. Guidance for the design/application of such metering systems, considered as applied to each time period t, is provided in Appendix 2.

Frequency of monitoring/recording	Follow those for parameters $EFkwTOD_{j,,j,t,y}$ in equation 5 and $EFkwAI_{j,,j,s,y}$ in equation 7
QA/QC procedures to be applied	
Purpose of data	Calculation of project emissions
Calculation method:	Follow those for parameters $EFkwTOD_{j,,j,t,y}$ in equation 5 and $EFkwAI_{j,,j,s,y}$ in equation 8
Comments:	Follow those for parameters $EFkwTOD_{j,,j,t,y}$ in equation 5 and $EFkwAI_{j,,j,s,y}$ in equation 8 Applicable only if PE emissions are to be calculated on a time-of-day basis when also incorporating charging systems' associated infrastructure sources on a net metered basis.

Data / Parameter	$LECT_{j,,j,t,\ y}$
Data unit	kwh/time period *t*
Description	Electricity provided to the grid and/or building from on-site storage battery during time-of-day period t within region j serving applicable fleet i in project year y (kwh/year)
Equations	9
Source of data	From on-site battery/charging system's adequate measurement systems
Description of measurement methods and procedures to be applied	Project metering systems' calibration must be conducted according to the equipment manufacturer's specifications. Projects must incorporate adequate metering systems when applying Eq 9. Guidance for the design/application of such metering systems, considered as applied to each time period t, is provided in Appendix 2.
Frequency of monitoring/recording	Measured actual data must be monitored and recorded on at least an annual basis.
QA/QC procedures to be applied	The consistency of such kwh should be cross-checked with other information sources where applicable
Purpose of data	Calculation of project emissions
Calculation method:	
Comments:	Applicable only if PE emissions are to be calculated on a net metered basis integrating multiple associated infrastructure sources, s.

Data / Parameter	$EFkwTODonsitebatt_{i,j,s,t,y}$
Data unit	tCO_2e/kwh
Description	Emission factor for the electricity from the on-site battery during time-of-day period t (both on-site infrastructure and EV on-board batteries) associated infrastructure source s within region j consumed by project chargers serving applicable fleet i in year y
Equations	9
Source of data	See data sources for Equation 8 variables above
Description of measurement methods and procedures to be applied	The emission factors for one associated infrastructure source -- for the on-site battery -- are calculated using the net weighted average of the grid and on-site renewable emission factors given using equation 8, but this time applied for each time-of-day period t On-site storage battery must assume the weighted average emission factor based upon the proportionate net consumption of grid and dedicated renewable energy at the charging system (using equation 9 applied during each time of day period basis) Projects must incorporate adequate metering systems when applying Eq 9. Guidance for the design/application of such metering systems, considered as applied to each time period t, is provided in Appendix 2.
Frequency of monitoring/recording	Consistent with the practices applied for monitoring the $EFkwTOD\text{-}AI_{i,j,s,t,y}$ in equation 9
QA/QC procedures to be applied	As for equation 8 variables
Purpose of data	Calculation of project emissions
Calculation method:	
Comments:	Applicable only if PE emissions are to be calculated on a metered basis integrating multiple associated infrastructure sources, s, on a time-of-day basis.

Data / Parameter	D_y
Data unit	%
Description	Discount factor to be applied in year y
Equations	10 and 11
Source of data	See data sources for data parameters in equation 13

Description of measurement methods and procedures to be applied	Discount factor applied if GHG credits have been issued in the project region for GHG credits issued for projects that introduce EV fleets (e.g. using the CDM AMS-III.C EV fleet methodology)
Frequency of monitoring/recording	Annual
QA/QC procedures to be applied	
Purpose of data	Calculation of emission reductions
Calculation method:	Look up value
Comments:	If there are no GHG credits issued for projects that introduce EV fleets in the project region, D_y must be 1 (ie there is no discount applied). Private networks can also demonstrate that D = 1 if there is no access to chargers beyond a defined set of EV's for which it can be demonstrated that no GHG credits from projects that introduce EV fleets have been issued. See guidance in section 8.4 regarding open and closed networks. If GHG credits have been issued for projects that introduce EV fleets for a region larger than the proposed EV charging project (e.g. the project introducing EVs is US-wide while the EV charging system project is confined to one state), then a sensible pro-rata share of the GHG credits issued to projects that introduce EV fleets can be made (e.g. using the pro-rata number of EV's on the road in the EV charging system project state compared to the total in the US, using sources such as ZEVFacts.com).

Data / Parameter	ERC_y
Data unit	tCO_2e
Description	Sum of GHG credits issued by all projects under this methodology (or others which support the introduction of EV charging systems) across this project's applicable fleet *i* categories within this total project region in project year y-1
Equations	11
Source of data	VCS (and other voluntary and regulated credit registries if they develop similar EV charging system methodologies), with GHG credits issued from EV charging system projects within this same project's region (e.g. for complementary charging networks)

Description of measurement methods and procedures to be applied	Simple tallies of the total GHG credits issued from EV charging system project year 1 through year y-1 within this project's region These GHG credits include those issued under this VCS charging system methodology (or similar ones developed by other certification groups) whose credits arise within the same region as this project but cover credits issued from complementary charging network systems (e.g. workplace chargers from a complementary project located in the same region as this project's residential chargers).
Frequency of monitoring/recording	Annual
QA/QC procedures to be applied	
Purpose of data	Calculation of emission reductions
Calculation method:	Look up values
Comments:	N/A

Data / Parameter	ERF_y
Data unit	tCO_2e
Description	Sum of GHG credits issued by all projects under methodologies which support the introduction of EV fleets (e.g., CDM AMS.III.C) within this project's same total region where the applicable fleet *i* categories are the same for both this EV charging system project and projects introducing EV fleets, in project year y-1
Equations	11
Source of data	VCS and other voluntary and regulated credit registries, with GHG credits issued from projects that introduce EV fleets within the project region
Description of measurement methods and procedures to be applied	Simple tallies of the total GHG credits issued for projects that introduce EV fleets within this project's region from project year 1 through year y-1 These GHG credits are those issued under EV fleet methodologies such as CDM AMS-III.C whose credit potentially double count with those issued through EV charging system projects where the applicable fleet of the EV charging system project include those that were introduced in the EV fleet project
Frequency of monitoring/recording	Annual

QA/QC procedures to be applied	
Purpose of data	Calculation of emission reductions
Calculation method:	
Comments:	If GHG credits have been issued projects introducing EV fleets for a region larger than the proposed EV charging system project (e.g. the project introducing EVs s US-wide while the EV charging system project is confined to one state), then a sensible pro-rata share of the GHG credits issued to the project that introduced EV fleets can be made (e.g. using the pro-rata number of EV's on the road in the EV charging system project state compared to the total in the US, using sources such as ZEVFacts.com).

9.3 Description of the Monitoring Plan

The project proponent must establish, maintain and apply a monitoring plan and GHG information system that includes criteria and procedures for obtaining, recording, compiling and analyzing data, parameters and other information important for quantifying and reporting GHG emissions.

All data collected as part of monitoring should be archived electronically and be kept at least for two years after the end of the last project crediting period. All data must be monitored unless indicated otherwise in the tables above.

Project reporting must include the following information for EV charging systems included in a project:

For activities monitored once up-front during project validation or as new project activity instances are admitted to a grouped project during verification:

1) Inventory and geographic location for each EV charging system included in the project.
2) Where EV charging systems' AI is utilized to provide electricity to EVs, in order to store and dispatch electricity to and from multiple sources, both on site and regionally, the monitoring plan must include plans for how data will be processed from the AI's metering systems (e.g., meters/sub-meters and/or associated measurement systems). Guidance for such metering is provided in Appendix 2.
3) Review of any previously issued VCUs for EV charging projects to verify that there is no overlap of ownership with chargers included in the project description, for example, using the unique EV charging identifiers supplied in the project description's EV charging system inventory. For grouped projects, such verification must apply to any new project activity instances and for new chargers subsequently added to the grouped project (e.g.,

by referencing the unique EV charging identifiers for these new project activity instances in project monitoring reports).

4) Review of any previously issued EV fleet credits to confirm the value established for the discount factor, *Dy*.

For activities monitored each year during verification for credit issuance:

1) Data on electricity consumption consistent with guidance provided in the parameter boxes above for each EV charger, which must be reported in a consistent manner with supporting data, such as invoices or utility or on site meter records. Where projects include LDV and HDV applicable fleets, electricity consumption must be monitored separately.

2) Supporting documentation used to determine parameters for use in quantification of annual baseline emissions if default factors (per Appendix 1) are not used.

The project proponent must establish and apply quality management procedures to manage data and information. Written procedures must be established for each measurement task outlining responsibility, timing and record location requirements. Record keeping practices must include:

- Electronic recording of values of logged parameters for each monitoring period
- Offsite electronic back-up of all logged data
- Maintenance of all documents and records in a secure and retrievable manner for at least two years after the end of the project crediting period.

Quality assurance/quality control procedures must also be applied to add confidence that all measurements and calculations have been made correctly. These may include, but are not limited to:

- Protecting monitoring equipment (sealed meters and data loggers)
- Protecting records of monitored data (hard copy and electronic storage)
- Checking data integrity on a regular and periodic basis (manual assessment, comparing redundant metered data, and detection of outstanding data/records)
- Comparing current estimates with previous estimates to identify any abnormal readings
- Providing sufficient training to project participants to install and maintain project devices
- Establishing minimum experience and requirements for operators in charge of project and monitoring
- Performing recalculations to make sure no mathematical errors have been made

APPENDIX 1: CALCULATION OF BASELINE DEFAULT VALUES FOR THE US AND CANADA

This appendix outlines the basis for the calculation of the optional default values used in the baseline emission calculations for U.S. LDV and HDV projects, and Canadian HDV projects. Values used to calculate the default value results were presented to the VVB via a separate Excel workbook during the approval process of the methodology.

Projects must apply the default value using units for EF (CO_2 or CO_2e) consistent with their project boundary choices, consistent across all project activity sources.

LDV Weighted Averages in the United States

Weighted averages for LDVs are based upon:

- The total number of each BEV and PHEV model on the road by end of 2015, based upon cumulative US sales data for 2010-2015 sourced from Argonne National Laboratories' monthly emails and web site[42]
- Kwh/100 mile and MPG ratings sourced from www.fueleconomy.gov or the 2016 Fuel Economy Guide, https://www.fueleconomy.gov/feg/pdfs/guides/FEG2016.pdf
- Gasoline was the fuel which the comparable fossil fuel cars consumed

The simple weighted average has been calculated for each applicable fleet (BEV+PHEV and BEV) based upon the number of EV models of each type on the road by end of 2015 multiplied by its corresponding kwh/100 mile value (AFEC) and equivalent fossil fuel vehicle's MPG value (MPG), which are listed in the table below.

Table A1: LDV Project Default Value Table

Applicable fleet	$AFEC_{iy}$	MPG_{jy}	EF_{jy}
L1/L2 (BEV and PHEV average)	33.32	29.18	19.56 lbs CO2/gal = 0.0088 tCO2/gal or 0.0088 tCO_2e/gal
DCFC (BEV average)	31.88	29.10	19.56 lbs CO2/gal = 0.0088 tCO2e/gal or 0.0088 tCO_2e/gal

HDV Weighted Averages in the United States

Each of these e-bus and e-truck weighted averages are based upon:

- The total number of each e-bus and e-truck models on the road in the US by beginning of 2017, based upon on data sourced from IHS Markit

[42] Argonne National Lab's (ANL) monthly emails uses data sourced from the hybridcars.com web site: http://www.hybridcars.com/december-2016-dashboard/ The main ANL web link is found here including the email address for the database manager: https://www.anl.gov/energy-systems/project/light-duty-electric-drive-vehicles-monthly-sales-updates

- The corresponding GWV classification for each model of e-bus and e-truck on the road, based upon data sourced from IHS Markit
- Kwh/mile data sourced for e-buses from commercial sources (confidential) and for e-trucks from Smith Electric and NREL reports for e-delivery truck vehicles as follows:
    - http://insideevs.com/smith-electric-vehicles-distance-energy-consumption/
    - http://www.nrel.gov/docs/fy17osti/66382.pdf
- Average MPG ratings for the corresponding class of MDV/HDV, as sourced from independent academic sources, specifically: https://www.nap.edu/read/12845/chapter/4#18
- Diesel fuel was the dominant baseline bus and truck fuel

The simple weighted average is calculated for each applicable fleet (e-bus and e-truck) based upon the number of EV models of each type on the road by beginning of 2017 multiplied by its corresponding kwh/100 mile value (AFEC) and equivalent GWV class of fossil fuel vehicle's average MPG value (MPG), which are listed in the table below.

Table A2: HDV Project Default Value Table

Applicable fleet	$AFEC_{iy}$	MPG_{jy}	EF_{jy}
e-buses	300	4.34	22.4 lbs CO2/gal = 0.0102 tCO2/gal or 0.0102 tCO_2e/gal
e-trucks	140	8.60	22.4 lbs CO2/gal = 0.0102 tCO2e/gal or 0.0102 tCO_2e/gal

LDV Weighted Averages in Canada

These weighted averages are based upon:

- The total number of each BEV and PHEV model on the road by end of 2016, based upon cumulative Canada data; kwh/100 mile and MPG ratings, all sourced from Natural Resources Canada
- Gasoline was the fuel which the comparable fossil fuel cars consumed

The simple weighted average has been calculated for each applicable fleet (BEV+PHEV and BEV) based upon the number of EV models of each type on the road by beginning of 2017 multiplied by its corresponding kwh/100 mile value (AFEC) and equivalent fossil fuel vehicle's MPG value (MPG), which are listed in the table below.

Table A3: LDV Project Default Value Table for Canada

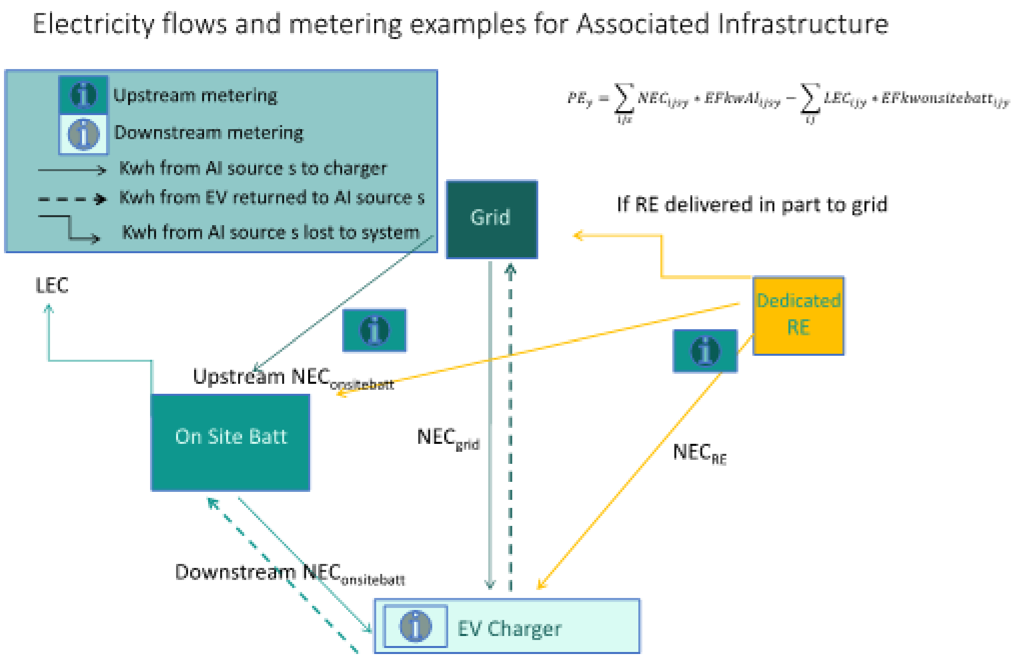
Applicable fleet	$AFEC_{iy}$	MPG_{jy}	EF_{jy}
L1/L2 (BEV and PHEV average)	35.44	29.65	19.56 lbs CO_2/gal = 0.0088 tCO_2/gal or 0.0088 tCO_2e/gal

DCFC (BEV average)	33.00	27.71	19.56 lbs CO_2/ga = 0.0088 tCO_2/gall or 0.0088 tCO_2e/gal

APPENDIX 2: GUIDANCE FOR DESIGN OF ADEQUATE METERING SYSTEMS FOR AI PROJECTS

This appendix outlines guidance for the design and application of metering systems of charging systems to adequately measure electricity exchanges when associated infrastructure (AI) is incorporated into projects when they apply to the determination of project emissions, as shown in Figure A1. If associated infrastructure is incorporated into the project boundary, PE equations 7, 8, or 9 are applicable.

Figure A1: Examples of Associated Infrastructure and Electricity Flows



When incorporating associated infrastructure, the charging system's metering system must adequately and accurately measure and trace the net electricity kwh provided to the charging system (i.e., deliveries minus receipts) from all electricity sourced from and returned to the grid, and the dedicated renewables. This may include dedicated renewable energy (e.g., on site) delivered to the EV directly and/or via on-site batteries, and net of kwh returned back to such sources from the EV batteries.

Note that metering systems for associated infrastructure can include "downstream" meters close to the EV, such as those provided by DCFC onboard meters (and referenced specifically in the ED parameter for kwh *delivered* by a charger to the EV which applies to the BE calculations), and "upstream" meters, located grid-side such as meters monitoring electricity (in kwh) delivered to the on-site batteries (which could be designed/applied to measure the kwh which a charger *consumes* in the EC parameter measurements which applies to the PE calculations).

Where the system's meters are located further "upstream", in order to not include any electricity lost to the EV charging system, any electricity sourced from associated infrastructure sources (notably from solar and the on-site battery) but delivered outside the EV charging system (e.g. delivered to the grid or the local building when the on-site battery is used as a back up generator source), must be sensibly taken into account for quantification. This includes the following examples:

1) Where the metered kwh to the on-site battery is located “upstream” on the grid side (rather than downstream of the on-site battery in the charger where electricity delivered to the EV is measured), any electricity that the on-site battery provides back to the grid, or its building in a given year must be measured and subtracted -- as LEC_{ijy} -- since these kwh represent losses to the overall charging system and do not result in EV miles driven.

2) Where the on-site battery is not connected to the grid or building (i.e., it does not serve as a power back up system), then the on-site battery does not need to be accounted for as a separate source, since it merely acts as a flow through for the grid and renewables sources. Any electricity received from the EV would also be returned to the EV. Therefore, the on-site battery would supply electricity consistent with the change in stored power between the year’s starting and end points which, compared to the kwh supplied by the grid and/or dedicated renewables, would be *de minimis*.

3) Any transfer of electricity from the EV to the onsite battery represent internal flows within the system and can be set aside since the electricity must either be returned downstream to the EV at a later date or tracked via LEC if subsequently delivered back to the grid via the on-site battery. Therefore, transfers of electricity from the EV to the onsite battery can be set aside.

4) Projects must be able to measure or sensibly estimate the electricity supplied from the grid and/or from dedicated renewable sources to the charger system and this may be a subset of the total electricity from this source. For example, the electricity delivered to the charging system may be less than the total electricity generated by the onsite renewables if these renewables also provide power back to the grid within a particular associated infrastructure system[43]. Similarly, the total grid electricity delivered to the system may be shared across both the EV charger if delivered directly while also supplying in parallel electricity to the on-site battery – the former contributing to NEC from the grid source and latter to NEC for the on-site battery.

Where the systems meters are located “downstream”, in order to not include any electricity lost to the EV charging system, any electricity sourced from associated infrastructure sources must be sensibly taken into account for quantification. This includes the following examples:

1) Although upstream-metering, (the measurement of kwh consumed by the chargers for parameter EC), typically applies for the PE calculations, the calculation of PE values can be made using downstream meters located in the chargers’ internal systems provided appropriate efficiency factors are applied to take account of chargers’ own electricity consumption. Where downstream measurement of PE is applied:

    - For PE calculations using downstream metering, consistent with the guidance in the parameter boxes for EC, ECTOD, NEC and NECT, efficiency factors must be applied to

[43] At a future date, projects may wish to consider issuing GHG credits for the subset of kwh delivered from the dedicated renewables to the grid (but not to the EV charger) using methodologies such as AMS-I.F https://cdm.unfccc.int/methodologies/DB/9KJWQ1G0WEG6LKHX21MLPS8BQR7242

account for potential efficiency losses due to the chargers' own kwh consumption. For L2s, such efficiency losses are de minimis[44] and so no efficiency factor is applied in the L2 EC, ECTOD, NEC and NECT parameter applications (since "downstream" meters would have de minimis variances with upstream meters). For DCFCs, if kwh data is sourced from "downstream" meters located within their own DCFCs internal smart meter systems (assuming as needed across these parameters that these smart meters are capable of differentiating inter alia the net kwh delivered to the EV's from each source s during time period t), then to establish the PE equation electricity *consumed* by the DCFC charger a DCFC default efficiency factor of 92.3% is applied to these internal smart DCFC metered kwh readings (i.e., using approach A in the parameter boxes)).

- Alternatively, DCFCs can use approach B applying "upstream" meter kwh measurements which are on the grid-side of the DCFC units/AI (e.g., for each source s and time period t).
- However, often relative to time-of-day periods *t* for NECT and ECTOD measurements, it is a DCFC's own "downstream" internal "smart" meters which have the most sophisticated metering capabilities for such time-of-day applications (whereupon approach A would be followed and the DCFC default efficiency factor applied).
- For DCFC using approach A, the default efficiency value applied would be the "downstream" smart meter's reading divided by the efficiency factor of 0.923 in order to estimate the kwh consumed by the DCFC fast charger on an "upstream kwh consumed" basis (as needed for the PE equations).
- If a project can demonstrate a more accurate efficiency factor for their particular DCFC systems (for example due to improvements in DCFC technology efficiencies over time), this updated accurate efficiency factor may be substituted for the 92.3% default efficiency value.

2) Where meters are located downstream for the measurement of NEC pertaining to the on-site battery, then the electricity measured must already be net of any LEC losses from the on-site battery to the grid – and thus LEC must be set at zero. This basis for such on-site battery net electricity measurements would be consistent with DCFC's measurement systems which track the electricity exchanges close the point of delivery to the EV. Additionally, for downstream metering, the electricity provided by the EV to the onsite battery must be measured for the calculation of NEC for the on-site battery (that is, it cannot be set aside for downstream metering).
3) Where the EV is delivering vehicle-to-grid (V2G) services where electricity from the car's on-board battery is returned directly to the grid, these EV-sourced electricity are netted out in the grid-sourced net-kwh (that is, in the calculation of NEC for the grid source *s*).
4) Where charging systems include simple associated infrastructure settings, such as residences using L1/L2 systems where "upstream" metering systems apply and where the associated infrastructure system elements can be limited (e.g. no on-site battery).

Note that the quantification of emissions from project associated infrastructure systems can be simplified using sensible estimates. For example, where a household residence has a solar panel

[44] Per INL: https://avt.inl.gov/evse-type/ac-level-2

that is grid-connected – which, while its total solar kwh production and grid-sales are metered, does not have a separate sub-meter to establish the solar kwh supplied to the EV charging system specifically -- it is acceptable to assume that the kwh delivered to the EV charger is the same weighted average as the solar/grid kwh mix the household itself consumed (i.e., sources whose electricity would have been separately metered). Utility-style modeling is also acceptable for settings where only the net electricity consumption/generation is measured for a household in order to establish the electricity delivered by both the grid and the on-site renewables and thus the required weighted average.

Methodology for Use of Foam Stabilized Base and Emulsion Asphalt Mixtures in Pavement Application

Version 1.0

24 June 2019

Sectoral Scope 6

This methodology was developed by the Smart Construction Center at the University of Maryland, in collaboration with Emissionairy, Inc., Chamberlain Contractors, Inc., and Straughan Environmental, Inc.

Authors:

Qingbin Cui, Associate Professor (cui@umd.edu, +1 301 405 8104)

Table of Contents

1 SUMMARY DESCRIPTION OF THE METHODOLOGY

Additionality and Crediting Method	
Additionality	Performance Method
Crediting Baseline	Performance Method

This methodology provides a framework for the quantification of greenhouse gas (GHG) emission reductions associated with the production and installation of Foam Stabilized Base (FSB) and/or asphalt emulsions as substitutes for Hot Mix Asphalt (HMA) in road construction projects located in the United States[1].

For over 40 years, FSB and asphalt emulsions have been used in road projects around the world when natural resources for virgin aggregate or funding to construct and maintain roads using HMA have been limited. In North America, where virgin aggregate has historically been easily accessible within proximity to project sites, FSB has not been as widely implemented as it has in other parts of the world. FSB has, therefore, been used on a very limited basis in the United States for the last 10 to 15 years. Most projects using FSB and asphalt emulsions in the United States are pilot projects funded by various state highway agencies. While these projects have proven successful, state highway administrations have been slow to accept and develop the protocol and practices for this approach in North America. Presently there are no national or regional standards for the production or application of FSB and asphalt emulsions, which serves as a major impediment to the acceptance and application of FSB and asphalt emulsions beyond the testing phase.

GHG emission reductions are generated from producing and applying FSB and asphalt emulsions versus HMA as follows:

- FSB and asphalt emulsions consist of 50% less liquid asphalt/bitumen by weight and 2.5% less asphalt/bitumen by volume than required for HMA production, reducing the reliance on resources. No virgin aggregates are required, eliminating the energy and resources needed for excavating machines and trucking. In most applications, but especially in rural areas, the GHG emissions from trucking are significantly reduced. This is due to the fact that FSB and asphalt emulsions can be manufactured on or close to the project site.
- Aggregates in FSB and asphalt emulsions do not have to be heated, while HMA liquid, which is roughly 2.2% of the total weight of the mix, needs to be heated up to 310 ºF.

[1] Under this methodology, the project proponent may be the technology owner, FSB producer/manufacturer, road owner, contractor, or other party associated with the production of application/construction or development of paving segments paved with FSB. Given that the project proponent could be any one of entities listed above, clear project ownership must be demonstrated through contractual agreements, or other arrangements, in order to avoid the risk of double counting with other participants in the supply chain.

In this methodology, performance benchmarks have been established for the determination of additionality and the crediting baseline. These benchmarks are based on GHG emissions from the baseline scenario, which enables a measurement of emission reduction potentials through the substitution of FSB and asphalt emulsions for HMA. Data from hot mix facilities and placement projects in different geographic locations within the United States were surveyed to determine the levels of the performance benchmarks. Emission reductions of FSB and asphalt emulsions are the differences between actual project emissions and the crediting performance benchmark.

2 DEFINITIONS

Aggregate
A collective term for the mineral materials such as sand, gravel and crushed stone that are used with a binding medium to form asphalt. Aggregate can be from either natural or recycled sources, called virgin aggregate or recycled aggregate.

Asphalt
A cementitious material, ranging from a dark brown to black color, in which the predominating constituents are bitumens that occur in nature or are obtained by petroleum processing

Asphalt Emulsions
A dispersion of small droplets of one liquid into another liquid. Usually, asphalt emulsions contain small droplets of asphalt binder in water and emulsifying agent. Standard asphalt emulsions contain 40% to 75% asphalt binder, 0.1% to 2.5% emulsifier, and 25% to 60% water.

Asphalt Pavement
Asphalt concrete layer(s) on supporting courses such as concrete base, asphalt treated base, cement treated base, granular base, and/or granular sub-base placed over the subgrade

Bitumen
A black or dark colored organic material with adhesive properties derived from distillation of petroleum or natural asphalt. Bitumen is also called liquid asphalt, asphalt binder, and/or liquid asphalt cement.

Cold Central Plant Recycling (CCPR)
A method for producing FSB and asphalt emulsions which requires milled reclaimed asphalt pavement (RAP) to be transported from an existing jobsite to a central mixing plant. The unheated RAP is then blended with foamed asphalt and a small amount of Portland cement in a cold mixing process.

Cold In-Place Recycling (CIR)
The principal method for producing FSB and asphalt emulsions which uses one or more mobile recycling machines for milling, asphalt production, and placement in a continuous operation at the pavement site. Generally, CIR uses 100% RAP generated from the existing pavement, which is

blended with small amount of Portland cement with a treatment depth ranging from approximately 2 to 6 inches.

Foamed Asphalt
A mixture of air, water, and bitumen. When injected with a small quantity of cold water, the hot bitumen expands explosively to about fifteen times its original volume and forms a fine mist or foam. In this foamed state, the bitumen has a very large surface area and an extremely low viscosity. This expanded bitumen mist is then incorporated into the mixing drum where the bitumen droplets are attracted to and coat the finer particles of pavement material, thus forming a mastic that effectively binds the mixture together.

Foamed Stabilized Base (FSB)
A mixture of foamed asphalt binder and RAP, or a combination of RAP and recycled concrete. Unlike hot mix asphalt (HMA), the foamed binder does not coat the aggregate particles. Rather, it coats the fines (passing #200 sieve) in the aggregate, which helps serve as a bonding agent to keep the aggregate particles together. FSB is generally used as a base course layer in the pavement construction in lieu of conventional HMA in order to reduce the carbon footprint of construction operations.

Full-Depth Reclamation (FDR)
A technique in which the full thickness of the asphalt pavement and a pre-determined portion of the underlying material (base, sub base, and/or subgrade) is uniformly pulverized and blended to provide an upgraded, homogenous base material. FDR is performed on the roadway without the addition of heat, similar to CIR. Thus, the emissions from FDR can be quantified using the same method as CIR.

Hot Mix Asphalt (HMA)
A mixture of course aggregate, fine aggregate, and asphalt cement that is produced at a central facility at temperatures between 300 and 325°F. HMA can incorporate a small amount of RAP (usually 10% to 30%) into the mix.

Portland Cement
The most common type of generally used cement around the world. It is used as a basic ingredient of concrete, mortar, stucco, and most non-specialty grout. It usually originates from limestone. Portland cement is a fine powder that consists of more than 90% ground Portland cement clinker, a limited amount of calcium sulfate (which controls the set time), and up to 5% minor constituents as allowed by various standards.

Reclaimed Asphalt Pavement (RAP)
Material generated from milling existing asphalt pavement layers during the rehabilitation of paved surfaces. RAP consists of aggregates that are coated by asphalt.

Structural Layer Coefficient
The relative structural capacity of a material per inch of thickness.

Virgin Aggregate
Aggregate that has been quarried and not used in any prior asphalt applications.

Warm Mix Asphalt (WMA)
A subcategory of HMA that is produced within a target temperature discharge range using the applicable state Department of Transportation (DOT) approved WMA additives or processes. The WMA technologies may be used as coating and compaction aids without lowering the production temperature.

3 APPLICABILITY CONDITIONS

This methodology is applicable under the following conditions:

1) Project activities include the construction of any type of road and/or parking lot (including parking lot patching projects) in the United States.
2) Project activities must apply one or more of the following processes for road construction:
    a) FSB produced using the CCPR process
    b) FSB produced using the CIR process
    c) FSB produced using the FDR process
    d) Asphalt emulsions produced using the CCPR process
    e) Asphalt emulsions produced using the CIR process
    f) Asphalt emulsions produced using the FDR process
3) Production plants where the project activity occurs may serve multiple pavement types, including, but not limited to, roadways and parking lots.
4) Project activities may have an HMA or WMA surface layer, but must have at least one FSB or asphalt emulsions base layer.

This methodology is not applicable under the following conditions:

1) Project activities include only an HMA, WMA, or other non-FSB/asphalt emulsions paving material base layer.

4 PROJECT BOUNDARY

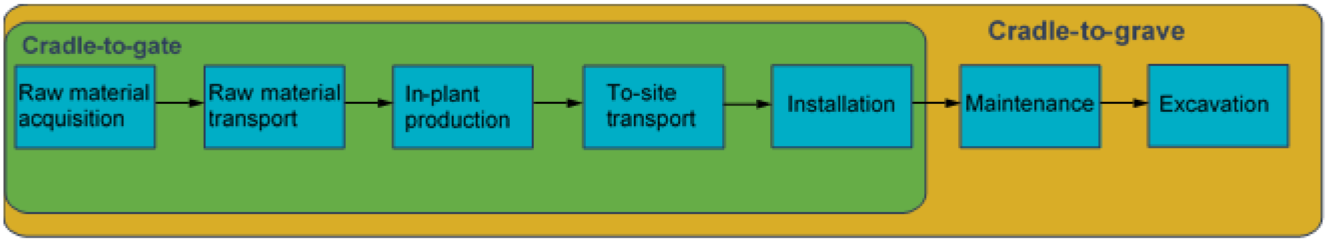
The spatial extent of the project boundary encompasses the stages from raw material acquisition to product installation and complies with the cradle-to-gate assessment principle (Sinden, 2008). As shown in Figure 1, the GHG impact of producing an asphalt mixture must be calculated by summing the following emission sources:

1) GHGs associated with manufacturing each of the constituent and ancillary materials;
2) GHGs from transporting materials from factory to mixing plant;

3) GHGs from all forms of energy involved in producing the asphalt at the mixing plant; and

4) GHGs from all forms of energy involved in milling the existing pavement and placing new pavement, including relevant transport activities.

Figure 1: Map of the Asphalt Life-Cycle

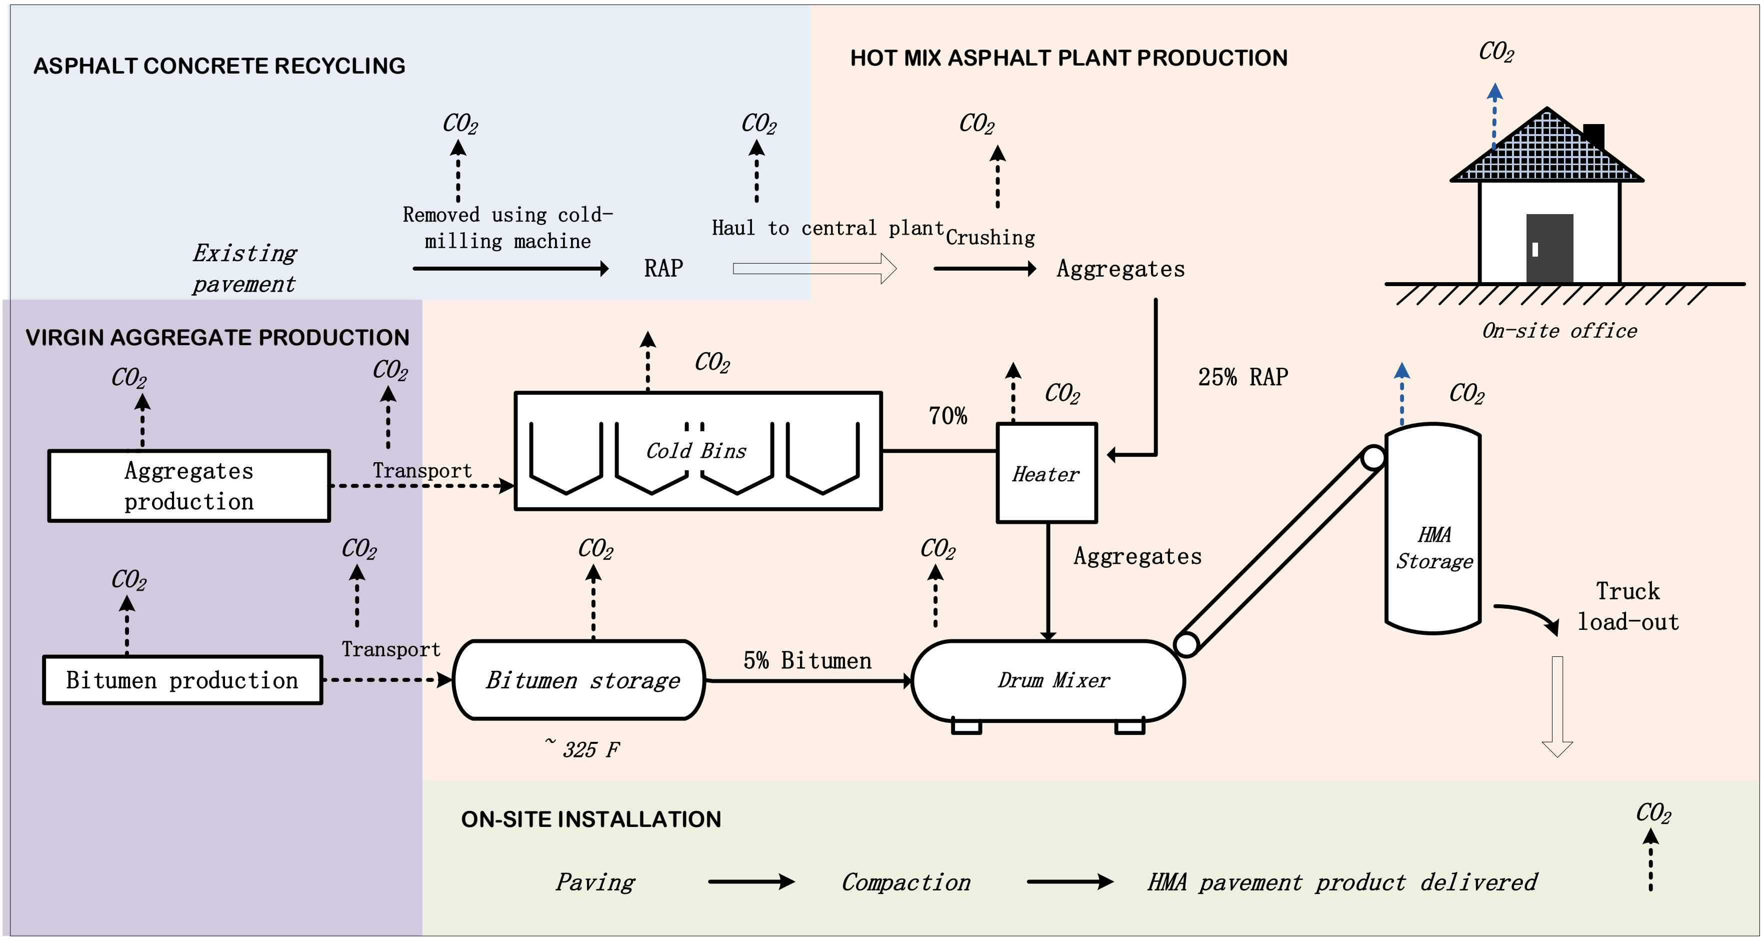


Maintenance and excavation of pavement is not included due to the high variability of maintenance practices in each region. Maintenance activities can be classified into preventive maintenance and structural improvement. Given the complexity of maintenance methods, material sources, and equipment use, associated GHG emissions vary significantly. The emission difference can only be captured after the maintenance activities are complete. As the structural performance of FSB and asphalt emulsions are comparable to the baseline HMA method, the frequency of pavement maintenance is generally the same (Bemanian et al., 2006; Morian et al., 2005). There is insignificant difference in post-installation emissions between FSB/asphalt emulsions and HMA. The boundary also excludes GHG emissions associated with the production of capital goods having lifetimes longer than one year and the transportation of employees to and from their normal place of work.

4.1 Boundary for Baseline Emissions

The estimation of baseline emissions for HMA projects begins with the production of raw materials at manufacturer sites and ends with the delivery of the final pavement product to the customer. It includes all energy-consuming activities of equipment and machinery at supplier sites, the hot mix facility, the job site, and associated transportation. The emission sources covered within the system boundary include production materials, manufacturing equipment/vehicles, operation of the plant office, and transport and storage of input materials (Sinden 2008). Specifically, the boundary for HMA systems consist of energy consumption for quarrying/producing the mineral aggregates and bitumen binder, transportation to and at the HMA production plant, storage, heating of the individual components (including aggregates and bitumen binder), mixing, and the transportation and installation of the mix at the job site, as shown in Figure 2.

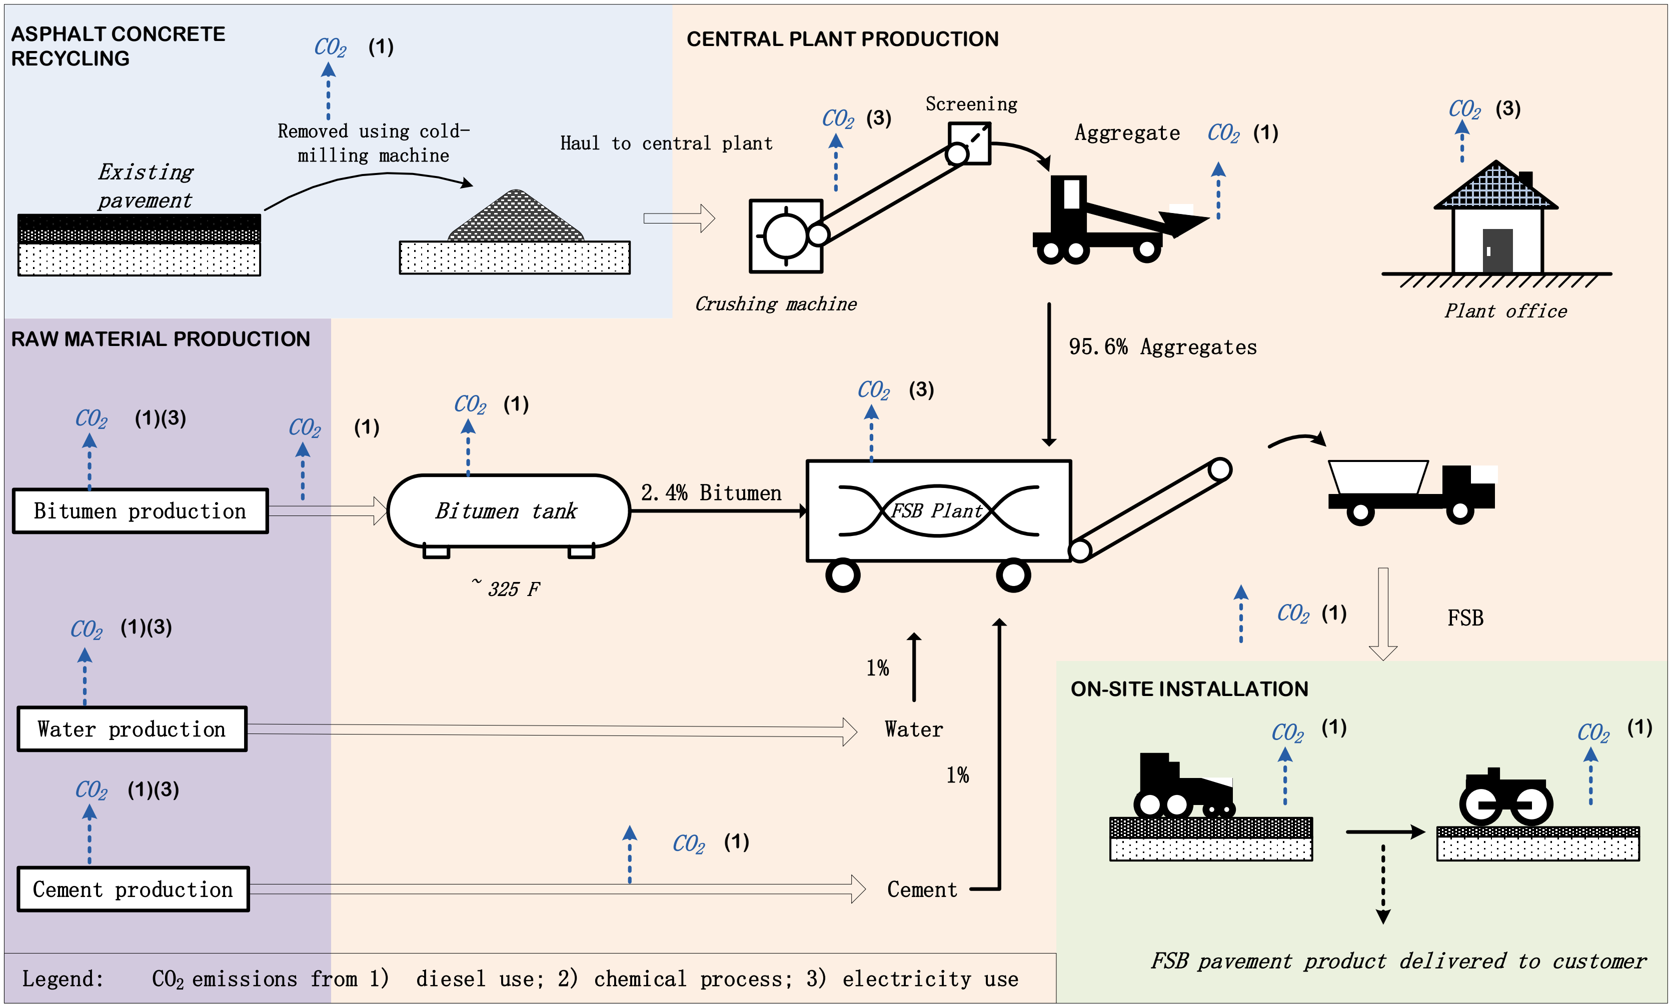
Figure 2: Diagram of HMA Production and Placement



4.2 Boundary for Project Emissions from CCPR Process

The estimation of project emissions for CCPR projects begins with the transportation of raw and recycled materials to a central plant and ends with the delivery of the final pavement product to the customer. CCPR projects transport milled materials from an existing jobsite to a central plant where FSB or asphalt emulsions are processed through a pug mill. Production of FSB begins with the crushing of RAP, which diverts waste from landfills. Once the crushed pavement is sized, the unheated RAP is then blended with foamed bitumen (or asphalt emulsions) and a small amount of Portland cement in a cold mixing process. Figure 3 shows the major processes included in a CCPR project. The boundary consists of the energy consumption for milling the existing pavement, producing bitumen binder and water, transportation to and at the FSB and asphalt emulsions production plant, heating of bitumen binder, mixing, transportation of materials and resources to the project site, and installation of the mix.

Figure 3: CCPR Project Activities and Associated GHG Sources

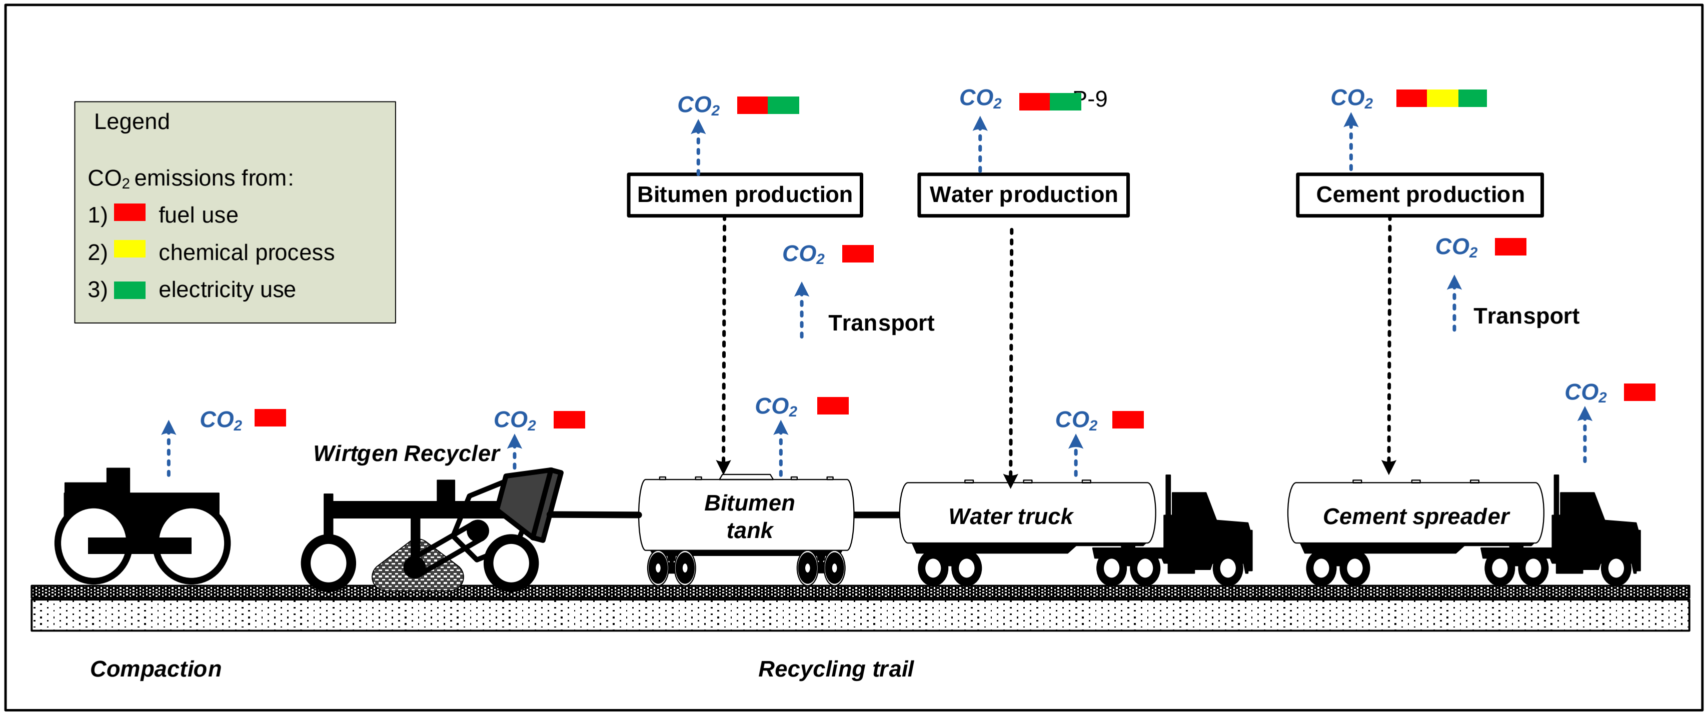


Note: Double-lined arrows signify included transportation; dashed-line arrows signify the separation of activities in different locations.

4.3 Boundary for Project Emissions from CIR and FDR Systems

The estimation of project emissions for CIR and FDR projects begins with the transportation of raw materials to a job site and ends with the delivery of the final pavement product to the customer. CIR and FDR use one or more mobile recycling machines for milling, production, and placement in a continuous operation at the pavement site. It reconstructs the roadways by using special equipment to mill up the existing pavement, mix it with hot bitumen oil (or asphalt emulsions) and additives, and then immediately place it back down on the road by permanent placement with a paver and rollers. CIR and FDR allows a paving contractor to use the aggregate from the existing road and, by adding liquid asphalt cement (consisting of under 3% of the total volume), it reduces the emissions of new aggregate materials and new liquid asphalt cement that must be shipped from the producer's plant site. Figure 4 shows the major activities included in CIR and FDR systems. The project boundary includes production of bitumen, water, and cement, operation of recycler and rollers, and transportation and storage of input materials.

Figure 4: CIR and FDR Project Activities and Associated GHG Sources



4.4 GHG Sources Included and Excluded from the Project Boundary

The greenhouse gases included in or excluded from the project boundary are shown in Table 1 below.

Table 1: GHG Sources Included or Excluded from the Project Boundary

Source		Gas	Included?	Justification/Explanation
HMA (Baseline)	Raw material acquisition	CO_2	Yes	GHGs are released from energy consumption in material manufacture process.
		CH_4	No	Not applicable
		N_2O	No	
	Raw material transport	CO_2	Yes	GHGs are released from fuel consumption for transporting materials from producers to central plant.
		CH_4	No	Not applicable
		N_2O	No	
	In-plant production	CO_2	Yes	GHGs are generated from the usage of natural gas by the drum mixer, plant electricity (including electricity for plant office), and diesel equipment/vehicles operated for producing HMA at the central plant.
		CH_4	No	Not applicable
		N_2O	No	
	To-site transport	CO_2	Yes	GHGs are released from fuel consumption for transporting materials from the central plant to construction site.
		CH_4	No	Not applicable
		N_2O	No	
	Installation	CO_2	Yes	GHGs are released from diesel consumption by construction equipment/vehicles, including asphalt paving machine, backhoe, bobcat/loader, sweeper/broom, air compressor, roller, trucks, etc.
		CH_4	No	Not applicable
		N_2O	No	

Source		Gas	Included?	Justification/Explanation
	Maintenance	CO_2	No	GHGs from maintenance and rehabilitation are excluded due to uncertain traffic volume, failure type and repair options.
		CH_4	No	Not applicable
		N_2O	No	
	Excavation	CO_2	No	GHGs from excavation are excluded due to the uncertainty in determining pavement disposal options (e.g., landfill, recycling, remain in place).
		CH_4	No	Not applicable
		N_2O	No	
CCPR (Project Scenario 1)	Raw material acquisition	CO_2	Yes	GHGs are released from energy consumption in material manufacture process.
		CH_4	No	Not applicable
		N_2O	No	
	Raw material transport	CO_2	Yes	GHGs are released from fuel consumption for transporting materials from producers to the central plant.
		CH_4	No	Not applicable
		N_2O	No	
	FSB/asphalt emulsions production	CO_2	Yes	GHGs are generated from the usage of electricity by plant office, bitumen heater and crusher and diesel equipment/vehicles operated for producing FSB/asphalt emulsions at the central plant.
		CH_4	No	Not applicable
		N_2O	No	
	To-site transport	CO_2	Yes	GHGs are released from fuel consumption for transporting materials from the central plant to the construction site.
		CH_4	No	Not applicable
		N_2O	No	
	Installation	CO_2	Yes	GHGs are released from fuel consumption by construction equipment/vehicles, including asphalt paving machine, backhoe,

		N_2O	No	

5 BASELINE SCENARIO

The baseline scenario for projects applying this methodology is the application of HMA, or the subcategory WMA, to both the surface and base layers. The emissions associated with the quarry, transportation, and production of HMA or WMA serve as performance benchmarks, which are identified in Table 3 of Section 6 below.[2]

CCPR, CIR, and FDR projects replace HMA or WMA base layers with FSB or asphalt emulsions. These processes typically outperform the performance benchmarks because they can reduce the emissions from producing bitumen and producing, transporting, and heating virgin aggregates.

6 ADDITIONALITY

Project proponents applying this methodology must determine additionality using the procedure described below:

Step 1: Regulatory Surplus

The project proponent must demonstrate regulatory surplus in accordance with the rules and requirements regarding regulatory surplus set out in the latest version of the *VCS Standard.*

Step 2: Performance Benchmark

[2] More than 94% of U.S. roads are paved with HMA (EPA, 2015). The National Asphalt Pavement Association (NAPA) statistics show that approximately one third of HMA projects in the U.S. in 2014 used WMA technologies (NAPA 2017). HMA and WMA typically requires that more than 70% virgin aggregates are used in HMA production. They need to be quarried, transported to the hot mix plant, sorted into cold bins, dried by the heaters, blended with hot bitumen binders, and then fed into a mixer. The emissions associated with a series of these processes serve as performance benchmarks.

There are three strata of performance benchmarks for additionality based on project types and one-way distances between the HMA plant and job site.

Stratum 1 is for patching projects with hauling distance less than 40 miles, while Stratum 2 is for patching projects with hauling distance greater than 40 miles. Stratum 3 is for roadway projects. The performance benchmarks for all three strata are summarized in Table 2 below. Appendix A describes the calculation of the performance benchmark for additionality.

Where a project emits less than the relevant predetermined benchmark set out below, the project is deemed to be additional. This is determined by comparing the project emission intensity (derived from Section 7.2 below) to the additionality performance benchmark.

Table 2: Performance Benchmark for Patching Projects and Roadway Projects (2014)

Stratum	Project type	Hauling distance	Additionality performance benchmark
1	Patching	≤ 40 miles	121.9 kgCO_2e/t
2	Patching	> 40 miles	142.4 kgCO_2e/t
3	Roadway	Undefined	95.1 kgCO_2e/t

Note: 1 kgCO_2e per tonne of output = 0.001 tCO_2e per tonne of output

The additionality performance benchmark is adjusted annually based on the expected changes in the use of RAP[3]. Based on NAPA (2017), the use of RAP in HMA is expected to increase by 1.1% every year. This increase can reduce carbon emissions by 0.1kgCO_2e/t (NAPA, 2012). Therefore, as shown in Table 3, the performance benchmark decreases by 0.1kgCO_2e/t annually.

Table 3: Performance Benchmarks from 2014 to 2025

	Patching Project (<40mile)	Patching Project (>40mile)	Roadway Project
2014	121.9	142.4	95.1
2015	121.8	142.3	95.0
2016	121.7	142.2	94.9
2017	121.6	142.1	94.8
2018	121.5	142.0	94.7
2019	121.4	141.9	94.6
2020	121.3	141.8	94.5

3 An increased use of RAP can reduce GHG emissions due to the use of more recycled materials thus reducing the need for mining, processing, and transporting crushed stone and bitumen binder.

2021	121.2	141.7	94.4
2022	121.1	141.6	94.3
2023	121.0	141.5	94.2
2024	120.9	141.4	94.1
2025	120.8	141.3	94.0

Note: Unit is $kgCO_2e/t$, where 1 $kgCO_2e$ per tonne of output = 0.001 tCO_2e per tonne of output

7 QUANTIFICATION OF GHG EMISSION REDUCTIONS

7.1 Baseline Emissions

Baseline emissions have been predetermined by the performance benchmark for the crediting baseline, which is the same as the additionality performance benchmark. The crediting baselines from 2014 to 2025 are presented in Table 4 below.

Similar to the additionality benchmark, there are three strata of performance benchmarks based on project types and one-way distances between the HMA plant and job site. Appendix A describes the calculation of the performance benchmark for the crediting baseline.

Table 4: Crediting Baseline for Estimation of Emission Reductions

	Patching Project (<40mile)	Patching Project (>40mile)	Roadway Project
2014	121.9	142.4	95.1
2015	121.8	142.3	95.0
2016	121.7	142.2	94.9
2017	121.6	142.1	94.8
2018	121.5	142.0	94.7
2019	121.4	141.9	94.6
2020	121.3	141.8	94.5
2021	121.2	141.7	94.4
2022	121.1	141.6	94.3
2023	121.0	141.5	94.2
2024	120.9	141.4	94.1
2025	120.8	141.3	94.0

Note: Unit: $kgCO_2e/t$. 1 $kgCO_2e$ per tonne of output = 0.001 tCO_2e per tonne of output

7.2 Project Emissions

Project emissions are calculated in one of two ways, depending on production method. Where the project is performed using CCPR, the calculation of project emissions must follow the process in Section 7.2.1. Where the project is performed using CIR or FDR, the calculation of project emissions must follow the process in Section 7.2.2.

7.2.1 Emissions from CCPR

CCPR emission intensity (*CCPR EI*) represents the quantity of GHGs emitted from producing and installing one metric ton of FSB and asphalt emulsions using CCPR. It is the summation of raw material production emission intensity (EI_M), to-plant delivery emissions intensity (EI_{PD}), in-plant production emission intensity (EI_P), to-site delivery emissions intensity (EI_{SD}) and on-site installation emission intensity (EI_I). *CCPR EI* is calculated as follows:

$$CCPR\ EI = EI_M + EI_{PD} + EI_{SD} + EI_P + EI_I \quad (1)$$

Where:

CCPR EI	=	Emission intensity of CCPR (kgCO_2e/t)
EI_M	=	Emission intensity of raw material production (kgCO_2e/t)
EI_{SD}	=	Emission intensity of to-site delivery (kgCO_2e/t)
EI_P	=	Emission intensity of in-plant production (kgCO_2e/t)
EI_I	=	Emission intensity of pavement installation (kgCO_2e/t)

Raw material production emission intensity[4] (EI_M) must be calculated as follows:

$$EI_M = \frac{EF_M \times W_M}{Project\ amount} \quad (2)$$

Where:

EI_M	=	Emission intensity of raw material production (kgCO_2e/t)
EF_M	=	Material emission factor (kgCO_2e/kg)
W_M	=	Material weight (kg)
Project amount	=	Amount of FSB/asphalt emulsions manufactured (t)

To-plant delivery emissions intensity (EI_{PD}) and to-site delivery emissions intensity (EI_{SD}) must be calculated according to Equation 3 and Equation 4. Where hauling distance is not directly

[4] It is reasonable to assume zero leakage because there is no difference in site preparation activities between baseline and project scenarios. Replacing HMA with FSB or asphalt emulsions for the pavement base layer does not entail a change in carbon efflux or carbon sink at the construction site.[5] It is reasonable to assume zero leakage because there is no difference in site preparation activities between baseline and project scenarios. Replacing HMA with FSB or asphalt emulsions for the pavement base layer does not entail a change in carbon efflux or carbon sink at the construction site.

monitored, the distance can be estimated using a map distance calculator. The addresses of the start point and destination must be documented. For conservativeness, a discount factor (DF) of 0.1 must be applied when a map distance calculator is used to estimate hauling distance (Hauling distance = Map distance × (1+DF)). DF is equal to 0 where using actual logged miles.

$$EI_{PD} = \frac{Trip_p \times Distance_P \times (1+DF) \times EF_T}{Project\ amount} \quad (3)$$

Where:

EI_{PD}	=	Emission intensity of to-plant delivery ($kgCO_2e/t$)
$Trip_P$	=	Number of trips from material manufacture to production plant
$Distance_P$	=	Distance to plant (mile)
DF	=	Discount factor
EF_T	=	Truck emission factor ($kgCO_2e$/mile)
Project amount	=	Amount of FSB/asphalt emulsions manufactured (t)

$$EI_{SD} = \frac{Trip_S \times Distance_S \times (1+DF) \times EF_T}{Project\ amount} \quad (4)$$

Where:

EI_{SD}	=	Emission intensity of to-site delivery ($kgCO_2e/t$)
$Trip_S$	=	Number of trips from production plant to job site
$Distance_S$	=	Distance to site (mile)
DF	=	Discount factor
EF_T	=	Truck emission factor ($kgCO_2e$/mile)
Project amount	=	Amount of FSB/asphalt emulsions manufactured (t)

In-plant production emission intensity (EI_P) includes the emissions from diesel and electricity consumption by plant equipment, vehicles, and the plant office.

Diesel users are often mixing machines, loaders, and dump trucks. Their emissions are calculated using Equations 5 and 6. Relevant emission factors are provided in Appendix B. Equipment operating hours must be logged to determine the amount of time it was used in the plant.

Electricity users are often the bitumen heater, RAP crusher, and plant office. Their emissions are calculated using Equation 8. Electricity emission factors can be found at the eGRID default emission factor database provided by the EPA. The electricity consumption must be recorded according to the electric meter.

$$EI_P = EI_D + EI_E \quad (5)$$

Where:

EI_P	=	Emission intensity of in-plant production ($kgCO_2e/t$)

EI_D	=	Emission intensity of diesel-consuming activities ($kgCO_2e/t$)
EI_E	=	Emission intensity of electricity-consuming activities ($kgCO_2e/t$)

$$EI_D = \frac{EF_{EQ} \times HR_{EQ}}{Project\ amount} \quad (6)$$

Where:

EI_D	=	Emission intensity of diesel-consuming activities ($kgCO_2e/t$)
EF_{EQ}	=	Equipment emission factor ($kgCO_2e/hour$)
HR_{EQ}	=	Equipment operation hours (hour)
Project amount	=	Amount of FSB/asphalt emulsions manufactured (t)

$$EI_E = \frac{EF_{EL} \times C_{EL}}{Project\ amount} \quad (7)$$

Where:

EI_E	=	Emission intensity of electricity-consuming activities ($kgCO_2e/t$)
EF_{EL}	=	Electricity emission factor ($kgCO_2e/kWh$)
C_{EL}	=	Electricity consumption (kWh)
Project amount	=	Amount of FSB/asphalt emulsions manufactured (t)

On-site installation emission intensity (EI_I) is due to diesel consumption from the equipment used for the installation project. The equipment includes milling machines, backhoes, loaders, sweepers, pavers, rollers, and trucks. Equipment emissions must be calculated using Equation 8. Relevant emission factors are provided in Appendix B. Where equipment operation hours are not available, labor hours can be used to approximate equipment operation hours according to Equation 10. Labor hours must be documented in the project daily log for verification. Conversion factors (CF) for commonly used equipment are listed in Section 9.1.1.

$$EI_I = \frac{EF_{EQ} \times HR_{EQ}}{Project\ amount} \quad (8)$$

Where:

EI_I	=	Emission intensity of pavement installation ($kgCO_2e/t$)
EF_{EQ}	=	Equipment emission factor ($kgCO_2e/hour$)
HR_{EQ}	=	Equipment operation hours (hour)
Project amount	=	Amount of FSB/asphalt emulsions installed (t)

$$HR_{EQ} = HR_{LA} \times CF \quad (9)$$

Where:

HR_{EQ}	=	Equipment operation hours (hour)

HR_{LA}	=	Labor hours (hour)
CF	=	Conversion factor

Note that CCPR projects may include more than one installation project because FSB and asphalt emulsions produced in central plants could be placed in a number of road areas. Where there are *i = 1,…, N* installation projects using FSB and asphalt emulsions from the same manufacturing process, the emission intensity of multiple CCPR projects (MCCPR EI) must be calculated as follows:

$$MCCPR\ EI = EI_M + EI_{PD} + EI_P + \frac{\sum_i^N EI_{SD,i} \cdot project\ amount_i + \sum_I^N EI_{I,i} \cdot project\ amount_i}{\sum_I^N project\ amount_i} \quad (10)$$

Where:

MCCPR EI	=	Emission intensity of multiple CCPR projects ($kgCO_2e/t$)
EI_M	=	Emission intensity of raw material production ($kgCO_2e/t$)
EI_{PD}	=	Emission intensity of to-plant delivery ($kgCO_2e/t$)
EI_P	=	Emission intensity of in-plant production ($kgCO_2e/t$)
EI_{SD}	=	To-site delivery emission intensity ($kgCO_2e/t$)
EI_I	=	On-site installation emission intensity ($kgCO_2e/t$)
Project amount	=	Amount of FSB and asphalt emulsions manufactured (t)

7.2.2 Emissions from CIR or FDR

CIR or FDR emission intensity (*CIR EI or FDR EI*) represents the quantity of GHGs emitted from producing and installing one metric ton of FSB or asphalt emulsions using CIR or FDR. *CIR EI* or *FDR EI* must calculated as follows:

$$CIR\ EI\ (or\ FDR\ EI) = EI_M + EI_{SD} + EI_I \quad (11)$$

Where:

CIR EI	=	Emission intensity of CIR ($kgCO_2e/t$)
FDR EI	=	Emission intensity of FDR ($kgCO_2e/t$)
EI_M	=	Material emissions intensity ($kgCO_2e/t$)
EI_{SD}	=	To-site delivery emission intensity ($kgCO_2e/t$)
EI_I	=	On-site installation emission intensity ($kgCO_2e/t$)

Material emissions intensity (EI_M) must be calculated using Equation 3 above.

To-site delivery emissions intensity (EI_{SD}) must be calculated using Equation 5 above.

On-site installation emissions intensity (EI_I) is derived from diesel consumption from the equipment used for the installation project. This equipment typically includes a cold recycler (e.g., Wirtgen 3800 CR), cement spreader, water truck, bitumen truck, vibratory roller, pneumatic roller, etc. The equipment emissions must be calculated using Equation 9 above. Relevant emission factors are provided in Appendix B.

Where project proponents cannot record the operating hours of all the equipment, the hours must be estimated using equipment running speeds according to Equation 13. The running speed of the cold recycler can be read from the screen on the machine. The water truck and bitumen truck are connected to the cold recycler to supply it with binding agents, and the rollers normally follow the train of equipment to compact the newly produced layer. Therefore, they can be assumed to run at the same speed as the cold recycler.

$$HR_{CR} = \frac{L}{S} \qquad (12)$$

Where:

HR_{CR}	=	Operation hours of cold recycler (hour)
S	=	Running speed of cold recycler (mile/hour)
L	=	Project length (mile)

Note that CIR and FDR projects may include more than one installation project because FSB and asphalt emulsion produced from CIR or FDR could be placed in a number of road sections. Where there are *i = 1,…, N* road sections using FSB and asphalt emulsion from the same CIR or FDR machinery, the emission intensity of multiple CIR or FDR projects (*MCIR EI* or *MFDR EI*) must be calculated as follows:

$$MCIR\ EI\ (or\ MFDR\ EI) = EI_M + \frac{\sum_i^N \boldsymbol{EI_{SD,i} \cdot project\ amount_i} + \sum_I^N \boldsymbol{EI_{I,i} \cdot project\ amount_i}}{\sum_I^N \boldsymbol{project\ amount_i}} \qquad (13)$$

Where:

MCIR EI	=	Emission intensity of multiple CIR projects ($kgCO_2e/t$)
MFDR EI	=	Emission intensity of multiple FDR projects ($kgCO_2e/t$)
EI_{SD}	=	To-site delivery emission intensity ($kgCO_2e/t$)
Project amount	=	Amount of FSB and asphalt emulsions manufactured (t)
EI_I	=	On-site installation emission intensity ($kgCO_2e/t$)

7.3 Leakage

Leakage is not considered an issue under this methodology, and is therefore set at zero.[5]

[5] It is reasonable to assume zero leakage because there is no difference in site preparation activities between baseline and project scenarios. Replacing HMA with FSB or asphalt emulsions for the pavement base layer does not entail a change in carbon efflux or carbon sink at the construction site.

7.4 Net GHG Emission Reductions and Removals

Net GHG emission reductions for FSB and asphalt emulsions are the emission intensity differences adjusted by the weight differences. The emission reductions must be calculated according to Equations 15 through 27.

A correction factor[6] (θ) of 1.02 for FSB and 1.17 for asphalt emulsions is applied. For projects that have a different structural layer coefficient and material density, the correction factor must be calculated as follows:

$$\theta = 0.0025\ DE\ /\ LC \tag{14}$$

Where:

DE	=	Density of FSB or asphalt emulsions, lb/cu.ft
LC	=	Layer coefficient of FSB or asphalt emulsions

Net GHG emission reductions for a single FSB project must be calculated as follows:

$$ER_{FSB-CCPR} = \left(\frac{CB}{\theta_{FSB}} - CCPR\ EI\right) \cdot \frac{project\ amount}{1{,}000} \tag{15}$$

Where:

$ER_{FSB\text{-}CCPR}$	=	Net emission reductions of FSB using CCPR (tCO_2e)
CB	=	Crediting baseline ($kgCO_2e/t$)
Θ_{FSB}	=	Correction factor for FSB (default value is 1.02)
CCPR EI	=	Emission intensity of CCPR project ($kgCO_2e/t$)
Project amount	=	Amount of FSB manufactured (t)

$$ER_{FSB-CIR} = \left(\frac{CB}{\theta_{FSB}} - CIR\ EI\right) \cdot \frac{project\ amount}{1{,}000} \tag{16}$$

Where:

$ER_{FSB\text{-}CIR}$	=	Net emission reductions of FSB using CIR (tCO_2e)

[6] The American Association of State Highway Transportation Officials (AASHTO) Design Guide is the recommended reference for the thickness design of cold in-place recycled asphalt mixes. The composition and structural properties of central plant recycled cold mix and cold in-place recycled paving materials are virtually the same; the range of structural layer coefficients recommended for recycled cold mixes (0.25 to 0.35) is also applicable for cold in-place recycled mixes. On average, various Departments of Transportation are considering a structural layer coefficient of 0.32 for FSB and of 0.30 for asphalt emulsion mixes (Schwartz and Khosravifar, 2013). The structural layer coefficient for a 0.75 inch HMA base mix is 0.40 (AASHTO, 1998). Accordingly, substituting FSB and asphalt emulsions for HMA on a project would, on average, require the FSB and asphalt emulsions layer to be approximately 25% (or 33%) thicker than the HMA layer. The densities of FSB, asphalt emulsions, and HMA are 130 lb/cu.ft, 140 lb/cu.ft and 160 lb/cu.ft, respectively. After factoring in these density differences, the use of FSB and asphalt emulsions must be 2% and 17% more than the HMA base by weight for the same length of paved road.

CB	=	Crediting baseline ($kgCO_2e/t$)
Θ_{FSB}	=	Correction factor for FSB (default value is 1.02)
CIR EI	=	Emission intensity of CIR project ($kgCO_2e/t$)
Project amount	=	Amount of FSB manufactured (t)

$$ER_{FSB-FDR} = \left(\frac{CB}{\theta_{FSB}} - FDR\ EI\right) \cdot \frac{project\ amount}{1{,}000} \quad (17)$$

Where:

$ER_{FSB\text{-}FDR}$	=	Net emission reductions of FSB using FDR (tCO_2e)
CB	=	Crediting baseline ($kgCO_2e/t$)
Θ_{FSB}	=	Correction factor for FSB (default value is 1.02)
FDR EI	=	Emission intensity of FDR project ($kgCO_2e/t$)
Project amount	=	Amount of FSB manufactured (t)

Net GHG emission reductions for multiple FSB projects must be calculated as follows:

$$ER_{FSB-CCPR} = \left(\frac{CB}{\theta_{FSB}} - MCCPR\ EI\right) \cdot \Sigma\ \frac{project\ amount_i}{1{,}000} \quad (18)$$

Where:

$ER_{FSB\text{-}CCPR}$	=	Net emission reductions of FSB using CCPR (tCO_2e)
CB	=	Crediting baseline ($kgCO_2e/t$)
Θ_{FSB}	=	Correction factor for FSB (default value is 1.02)
MCCPR EI	=	Emission intensity of multiple CCPR projects ($kgCO_2e/t$)
Project amount	=	Amount of FSB manufactured (t)

$$ER_{FSB-CIR} = \left(\frac{CB}{\theta_{FSB}} - MCIR\ EI\right) \cdot \Sigma\ \frac{project\ amount_i}{1{,}000} \quad (19)$$

Where:

$ER_{FSB\text{-}CIR}$	=	Net emission reductions of FSB using CIR (tCO_2e)
CB	=	Crediting baseline ($kgCO_2e/t$)
Θ_{FSB}	=	Correction factor for FSB (default value is 1.02)
MCIR EI	=	Emission intensity of multiple CIR projects ($kgCO_2e/t$)
Project amount	=	Amount of FSB manufactured (t)

$$ER_{FSB-FDR} = \left(\frac{CB}{\theta_{FSB}} - MFDR\ EI\right) \cdot \Sigma\ \frac{project\ amount_i}{1{,}000} \quad (20)$$

Where:

$ER_{FSB\text{-}FDR}$	=	Net emission reductions of FSB using FDR (tCO_2e)
CB	=	Crediting baseline ($kgCO_2e/t$)
Θ_{FSB}	=	Correction factor for FSB (default value is 1.02)
MFDR EI	=	Emission intensity of multiple FDR projects ($kgCO_2e/t$)
Project amount	=	Amount of FSB manufactured (t)

Net GHG emission reductions for a single asphalt emulsion project must be calculated as follows:

$$ER_{AE-CCPR} = \left(\frac{CB}{\theta_{AE}} - CCPR\ El\right) \cdot \frac{project\ amount}{1{,}000} \qquad (21)$$

Where:

$ER_{AE\text{-}CCPR}$	=	Net emission reductions of asphalt emulsions using CCPR (tCO_2e)
CB	=	Crediting baseline ($kgCO_2e/t$)
θ_{AE}	=	Correction factor for asphalt emulsion (default value is 1.17)
CCPR EI	=	Emission intensity of CCPR project ($kgCO_2e/t$)
Project amount	=	Amount of asphalt emulsions manufactured (t)

$$ER_{AE-CIR} = \left(\frac{CB}{\theta_{AE}} - CIR\ El\right) \cdot \frac{project\ amount}{1{,}000} \qquad (22)$$

Where:

$ER_{AE\text{-}CIR}$	=	Net emission reductions of asphalt emulsions using CIR (tCO_2e)
CB	=	Crediting baseline ($kgCO_2e/t$)
θ_{AE}	=	Correction factor for asphalt emulsion (default value is 1.17)
CIR EI	=	Emission intensity of CIR project ($kgCO_2e/t$)
Project amount	=	Amount of asphalt emulsions manufactured (t)

$$ER_{AE-FDR} = \left(\frac{CB}{\theta_{AE}} - FDR\ El\right) \cdot \frac{project\ amount}{1{,}000} \qquad (23)$$

Where:

$ER_{AE\text{-}FDR}$	=	Net emission reductions of asphalt emulsions using FDR (tCO_2e)
CB	=	Crediting baseline ($kgCO_2e/t$)
θ_{AE}	=	Correction factor for asphalt emulsion (default value is 1.17)
FDR EL	=	Emission intensity of FDR project ($kgCO_2e/t$)
Project amount	=	Amount of asphalt emulsions manufactured (t)

Net GHG emission reductions for multiple asphalt emulsion projects must be calculated as follows:

$$ER_{AE-CCPR} = \left(\frac{CB}{\theta_{AE}} - MCCPR\ El\right) \cdot \frac{project\ amount}{1{,}000} \tag{24}$$

Where:

$ER_{AE\text{-}CCPR}$	=	Net emission reductions of asphalt emulsions using CCPR (tCO_2e)
CB	=	Crediting baseline ($kgCO_2e/t$)
θ_{AE}	=	Correction factor for asphalt emulsion (default value is 1.17)
MCCPR EI	=	Emission intensity of multiple CCPR projects ($kgCO_2e/t$)
Project amount	=	Amount of asphalt emulsions manufactured (t)

$$ER_{AE-CIR} = \left(\frac{CB}{\theta_{AE}} - MCIR\ El\right) \cdot \frac{project\ amount}{1{,}000} \tag{25}$$

Where:

$ER_{AE\text{-}CIR}$	=	Net emission reductions of asphalt emulsions using CIR (tCO_2e)
CB	=	Crediting baseline ($kgCO_2e/t$)
θ_{AE}	=	Correction factor for asphalt emulsion (default value is 1.17)
MCIR EI	=	Emission intensity of multiple CIR projects ($kgCO_2e/t$)
Project amount	=	Amount of asphalt emulsions manufactured (t)

$$ER_{AE-FDR} = \left(\frac{CB}{\theta_{AE}} - MFDR\ El\right) \cdot \frac{project\ amount}{1{,}000} \tag{26}$$

Where:

$ER_{AE\text{-}FDR}$	=	Net emission reductions of asphalt emulsions using FDR (tCO_2e)
CB	=	Crediting baseline ($kgCO_2e/t$)
θ_{AE}	=	Correction factor for asphalt emulsion (default value is 1.17)
MFDR EI	=	Emission intensity of multiple FDR projects ($kgCO_2e/t$)
Project amount	=	Amount of asphalt emulsions manufactured (t)

8 MONITORING

The data parameters available at validation and those to be monitored are introduced and background information is provided in Sections 8.1 and 8.2, respectively. Section 8.3 describes general guidance for collecting and reporting all data and parameters listed in Section 8.2.

8.1 Parameters Available at Validation

8.1.1 Parameters available at validation for HMA and CCPR

Data / Parameter:	EF_M
Data unit	$kgCO_2e/kg$
Description	Material emission factor
Equations	2
Source of data	CMUGDI (2008)
Value applied	RAP: 0 Cement: 0.83 Bitumen: 0.48 Water: 0 Crushed rock: 0.056 Sand: 0.005 Manufactured aggregates: 0.006
Justification of choice of data or description of measurement methods and procedures applied	CMUGDI (2008) is comprised of national economic input-output models and publicly available resources use and emission data, which has been accessed over 1 million times by researchers or business users.
Purpose of Data	Calculation of material production emissions
Comments	Data to be updated when the material emissions factor is updated

Data / Parameter:	EF_T
Data unit	$kgCO_2e/mile$
Description	Truck's emission per mile travelled
Equations	3, 4
Source of data	TCR (2015)
Value applied	10.2
Justification of choice of data or description of measurement methods and procedures applied	Emission factors from TCR are compiled from publicly available data sources and updated each year to ensure that project proponents have the most accurate and up-to-date greenhouse gas data.
Purpose of Data	Calculation of baseline delivery emission Calculation of CCPR delivery emission
Comments	Data to be updated when the diesel emissions factor is updated

Data / Parameter:	EF_{EQ}

Data unit	$kgCO_2e/hr$
Description	Equipment emissions per hour
Equations	6, 8
Source of data	EPA (2012). "Engine Certification Data for Heavy Truck, Buses, and Engines."<http://www.epa.gov/oms/certdata.htm#largeng>.
Value applied	Appendix B
Justification of choice of data or description of measurement methods and procedures applied	The engine emission information is obtained from the EPA off-road engine certification database and further stratified equipment types by engine maker and horsepower rating. The database created for equipment emission estimation is presented in Appendix B
Purpose of Data	Calculation of baseline emission Calculation of CCPR emission
Comments	Data was collected one time and must be updated when more strict emission standard is implemented nationwide

Data / Parameter:	EF_{EL}
Data unit	$kgCO_2e/kWh$
Description	Electricity emission factor
Equations	7
Source of data	EPA (2017)
Value applied	Refer to EPA's eGRID summary tables for electricity emission factors for different regions
Justification of choice of data or description of measurement methods and procedures applied	Emission factors from eGRID summary tables are compiled by the EPA and updated each year to ensure that project proponents have the most accurate and up-to-date greenhouse gas data. The calculation of electricity emission must use region-specific emission factors.
Purpose of Data	Calculation of baseline emission Calculation of CCPR emission
Comments	The project proponent must use the most recent eGRID summary tables available.

Data / Parameter:	CF
Data unit	Between 0 and 1
Description	Conversion factor: the percentage of equipment operating time in the total labor time
Equations	9
Source of data	Liu et al. (2016)

Value applied	Milling machine: 0.66 Backhoe: 0.33 Loader: 0.33 Sweeper: 0.55 Paver: 0.50 Roller: 0.59 Truck: 1
Justification of choice of data or description of measurement methods and procedures applied	Three projects were observed on-site to count the effective operation time of each piece of equipment. The percentage utilization (PU) was calculated using the effective operation time divided by the total labor hours. The average *PU* values are 0.55 for the asphalt-milling machine; 0.10 for the backhoe; 0.10 for the bobcat/loader; 0.4 for the sweeper/broom; 0.10 for the excavator; 0.33 for the paver and 0.45 for the roller. Different *PU*s will produce different amounts of GHG emissions. According to a study by Lewis et al. (2009), the emission rate of idling equipment is about one quarter of the emission rate of the operating equipment. This difference is simplified and incorporated into the emission calculation as an average conversion factor (CF), which equals *PU+0.25(1-PU)*.
Purpose of Data	Calculation of baseline equipment emissions Calculation of CCPR equipment emissions
Comments	Data does not need to be updated

Data / Parameter:	DF
Data unit	Between 0 and 1
Description	For conservativeness, a discount factor (DF) must be applied when a map distance calculator is used to estimate hauling distance. DF is equal to 0 if using actual logged miles.
Equations	3, 4
Source of data	On-site observations
Value applied	0.1
Justification of choice of data or description of measurement methods and procedures applied	Ten projects were observed on site to count the distance between map and equipment odometer. Hauling distance = Map distance × (1+DF)
Purpose of Data	Calculation of baseline equipment emissions Calculation of CCPR equipment emissions
Comments	Data does not need to be updated

8.1.2 Parameters available at validation for CIR or FDR

Data / Parameter:	EF_T
Data unit	$kgCO_2e/mile$
Description	Truck's emission per mile travelled
Equations	3, 4
Source of data	TCR (2015)
Value applied	10.2
Justification of choice of data or description of measurement methods and procedures applied	Emission factors from TCR are compiled from publicly available data sources and updated each year to ensure that project proponents have the most accurate and up-to-date greenhouse gas data.
Purpose of Data	Calculation of CIR or FDR delivery emissions
Comments	Data to be updated when the diesel emissions factor is updated

Data / Parameter:	EF_M
Data unit	$kgCO_2e/kg$
Description	Material emission factor
Equations	1
Source of data	CMUGDI (2008)
Value applied	RAP: 0 Cement: 0.83 Bitumen: 0.48 Water: 0
Justification of choice of data or description of measurement methods and procedures applied	CMUGDI (2008) is comprised of national economic input-output models and publicly available resources use and emission data, which has been accessed over 1 million times by researchers or business users.
Purpose of Data	Calculation of material production emissions
Comments	Data to be updated when the material emissions factor is updated

Data / Parameter:	EF_{EQ}
Data unit	$kgCO_2e/hr$
Description	Equipment emission per hour
Equations	6, 7
Source of data	EPA (2012). "Engine Certification Data for Heavy Truck, Buses, and Engines."<http://www.epa.gov/oms/certdata.htm#largeng>.

Value applied	Appendix B
Justification of choice of data or description of measurement methods and procedures applied	The engine emission information is from the EPA off-road engine certification database and stratified by equipment type, engine make, and horsepower rating. The database created for equipment emission estimation is presented in Appendix B.
Purpose of Data	Calculation of CIR or FDR emission
Comments	Data was collected one time and must be updated when more strict emissions standards are implemented nationwide

8.2 Data and Parameters Monitored

8.2.1 Data and Parameters Monitored for HMA and CCPR

Data / Parameter	W_M
Data unit	Kg
Description	Quantity of each raw material used to produce HMA or FSB or asphalt emulsions
Equations	2
Source of data	Data source acquired through monitoring
Description of measurement methods and procedures to be applied	The data can be obtained from plant production records
Frequency of monitoring/recording	Once per project
QA/QC procedures to be applied	Cross-checking of reported quantity versus trucking manifests to confirm quality measurement.
Purpose of Data	Calculation of HMA material emissions Calculation of CCPR material emissions
Comments	

Data / Parameter	$Distance_P$
Data unit	Miles
Description	The total miles that trucks travelled to supply raw materials to HMA plant or FSB plant
Equations	3
Source of data	Data derived from monitoring
Description of measurement methods and procedures to be applied	Distance can be obtained from the daily report of truck drivers or measured by approximation

Frequency of monitoring/recording	Once per project
QA/QC procedures to be applied	Cross-checking of reported mileage versus trucking manifests to confirm quality measurement.
Purpose of Data	Calculation of HMA to-plant delivery emissions Calculation of CCPR to-plant delivery emission
Comments	

Data / Parameter	$Distance_S$
Data unit	Miles
Description	The total miles that trucks travelled to supply products to the job site
Equations	4
Source of data	Data derived from monitoring
Description of measurement methods and procedures to be applied	Distance can be obtained from the daily report of truck drivers or measured by approximation
Frequency of monitoring/recording	Once per project
QA/QC procedures to be applied	Cross-checking of reported mileage versus trucking manifests to confirm quality measurement.
Purpose of Data	Calculation of HMA to-site delivery emissions Calculation of CCPR to-site delivery emission
Comments	

Data / Parameter	C_{EL}
Data unit	*kWh*
Description	Electricity consumption of the whole plant
Equations	7
Source of data	Data derived through monitoring
Description of measurement methods and procedures to be applied	The use of electricity can be obtained from plant's utility bills
Frequency of monitoring/recording	Utility bills must be collected monthly or quarterly
QA/QC procedures to be applied	Cross-checking of reported consumption versus utility bills to confirm quality measurement.
Purpose of Data	Calculation of CCPR in-plant production emissions

Comments	

Data / Parameter	Project amount
Data unit	t
Description	Output quantity of FSB and asphalt emulsions
Equations	2, 3, 4, 6, 7, 8
Source of data	Data derived through monitoring
Description of measurement methods and procedures to be applied	Data can be reported according to plant production records
Frequency of monitoring/recording	Once per project
QA/QC procedures to be applied	Cross-checking of reported amount versus production logs to confirm quality measurement.
Purpose of Data	Calculation of CCPR emission
Comments	

Data / Parameter	HR_{EQ}
Data unit	Hour
Description	Total operating hours of on-site use of equipment
Equations	8
Source of data	Data derived through monitoring
Description of measurement methods and procedures to be applied	Data can be obtained from daily report of on-site contractors
Frequency of monitoring/recording	Once per project
QA/QC procedures to be applied	Cross-checking of reported data versus labor hours to confirm quality measurement.
Purpose of Data	Calculation of HMA equipment emissions Calculation of CCPR equipment emissions
Comments	Data does not need to be updated

Data / Parameter	HR_{LA}
Data unit	Hour
Description	Total labor hours of on-site use of equipment
Equations	9

Source of data	Data derived from monitoring
Description of measurement methods and procedures to be applied	Labor hours can be obtained from the daily reports of contractors
Frequency of monitoring/recording	Once per project
QA/QC procedures to be applied	Cross-checking of reported hours versus daily reports to confirm quality measurement.
Purpose of Data	Calculation of HMA installation emissions Calculation of CCPR installation emission
Comments	

Data / Parameter	DE
Data unit	lb/cu.ft
Description	Density of FSB or asphalt emulsions
Equations	14
Source of data	Data derived from monitoring
Description of measurement methods and procedures to be applied	Density data can be obtained from project specifications
Frequency of monitoring/recording	Once per project
QA/QC procedures to be applied	Cross-checking of reported data versus theoretical density to confirm quality measurement.
Purpose of Data	Calculation of CCPR emission reduction
Comments	

Data / Parameter	LC
Data unit	
Description	Layer coefficient of FSB or asphalt emulsions
Equations	14
Source of data	Data derived from monitoring
Description of measurement methods and procedures to be applied	Layer coefficient can be obtained from project specifications
Frequency of monitoring/recording	Once per project

QA/QC procedures to be applied	Cross-checking of reported data versus DOT commonly used coefficients to confirm quality measurement.
Purpose of Data	Calculation of CCPR emission reduction
Comments	

8.2.2 Data and Parameters Monitored for CIR or FDR

Data / Parameter:	W_M
Data unit	Kg
Description	The weight of each raw material used to produce FSB or asphalt emulsions
Equations	2
Source of data	Data derived from monitoring
Description of measurement methods and procedures to be applied	The data can be obtained from project records.
Frequency of monitoring/recording	Once per project
QA/QC procedures to be applied	Cross-checking of reported quantity versus trucking manifests to confirm quality measurement.
Purpose of Data	Calculation of CIR or FDR material emissions
Comments	Data does not need to be updated

Data / Parameter	Project amount
Data unit	T
Description	Output quantity of FSB and asphalt emulsions
Equations	2, 4, 6
Source of data	Data derived through monitoring
Description of measurement methods and procedures to be applied	The data can be reported according to plant production records
Frequency of monitoring/recording	Once per project
QA/QC procedures to be applied	Cross-checking of reported quantity versus trucking manifests to confirm quality measurement.
Purpose of Data	Calculation of CIR or FDR emission
Comments	

Data / Parameter:	L
Data unit	Miles
Description	Length of damaged pavement
Equations	11
Source of data	Data derived from monitoring
Description of measurement methods and procedures to be applied	The data can be obtained from project records
Frequency of monitoring/recording	Once per project
QA/QC procedures to be applied	Cross-checking of reported mileage versus map distance to confirm quality measurement.
Purpose of Data	Calculation of CIR or FDR installation emissions
Comments	

Data / Parameter:	Distance
Data unit	Miles
Description	The total miles that trucks travelled to supply raw materials to the job site
Equations	6
Source of data	Data derived from monitoring on site
Description of measurement methods and procedures to be applied	Distance can be obtained from the daily report of truck drivers or measured by approximation
Frequency of monitoring/recording	Once per project
QA/QC procedures to be applied	Cross-checking of reported mileage versus trucking manifests to confirm quality measurement.
Purpose of Data	Calculation of CIR or FDR to-site delivery emissions
Comments	

Data / Parameter:	S
Data unit	Mph
Description	Running speed of cold recycler
Equations	11

Source of data	Data derived from monitoring project site
Description of measurement methods and procedures to be applied	The data can be obtained from project records
Frequency of monitoring/recording	Once per project
QA/QC procedures to be applied	Cross-checking of reported speed versus driver's log to confirm quality measurement.
Purpose of Data	Calculation of CIR or FDR installation emissions
Comments	

Data / Parameter	DE
Data unit	lb/cu.ft
Description	Density of FSB or asphalt emulsions
Equations	14
Source of data	Data derived from monitoring
Description of measurement methods and procedures to be applied	Density data can be obtained from project specifications
Frequency of monitoring/recording	Once per project
QA/QC procedures to be applied	Cross-checking of reported data versus theoretical density to confirm quality measurement.
Purpose of Data	Calculation of CIR or FDR emission reduction
Comments	

Data / Parameter	LC
Data unit	
Description	Layer coefficient of FSB or asphalt emulsions
Equations	14
Source of data	Data derived from monitoring
Description of measurement methods and procedures to be applied	Layer coefficient can be obtained from project specifications
Frequency of monitoring/recording	Once per project
QA/QC procedures to be applied	Cross-checking of reported data versus DOT commonly used coefficients to confirm quality measurement.

Purpose of Data	Calculation of CIR or FDR emission reduction
Comments	

8.3 Description of the Monitoring and Quality Assurance Plan

Project proponents must detail the procedures for collecting and reporting all data and parameters listed in Section 8.2. Input data must be checked for typical errors, including inconsistent physical units, unit conversion errors, transcription errors, and missing data for specific time periods or physical units.

All data collected as a part of monitoring process must be archived electronically and be kept at least for two years after the end of the last project crediting period. All direct measurements must be conducted with calibrated measurement equipment according to relevant industry standards. Where direct measurements are not applied, project proponents must demonstrate that the values used for the project are reasonably conservative, considering the uncertainty associated with these values.

Quality assurance/quality control procedures must also be applied to add confidence that all measurements and calculations have been made correctly. These may include, but are not limited to:

- Protecting records of monitored data (hard copy and electronic storage)
- Checking data integrity on a regular and periodic basis (manual assessment, comparing redundant metered data, and detection of outstanding data/records)
- Comparing current estimates with previous estimates to identify any abnormal readings
- Providing sufficient training to project participants to install and maintain project devices
- Establishing minimum experience and requirements for operators in charge of project and monitoring
- Performing recalculations to make sure no mathematical errors have been made.

APPENDIX A: DETERMINATION OF PERFORMANCE BENCHMARK FOR ADDITIONALITY AND CREDITING BASELINE

Quantification of Baseline Emissions

The performance benchmark determined for use in this methodology represents the quantity of GHGs emitted from producing and installing one metric ton of HMA. This was calculated based on emission intensities that sum the material emission intensity, to-plant delivery emissions intensity, in-plant production emission intensity, to-site delivery emissions intensity, and on-site installation emission intensity.

The component materials of HMA include bitumen binders, crushed rock, sand, gravel, RAP and manufactured aggregates. GHG emissions from material production and transportation include:

1) The embodied GHG emissions of construction materials, which are primarily from energy consumption and chemical combustion associated with material production; and,

2) GHG emissions from fuel consumption for transporting materials to production facilities.

Primary equipment/vehicles used for placing HMA include asphalt paving machines, backhoes, bobcat/loaders, sweeper/brooms, air compressors, rollers, trucks, etc. Equipment operation information was gathered from projects sampled using HMA. For each project, the operation information for trucks, which deliver the hot mix to the job site and carry the RAP from the job site to the hot mix plant, was obtained from truck driver reports. The truck driver reports record time in and out from the job site for each truck, the total mileage travelled, and the gallons of diesel used by each truck. The recorded information was then used for estimating the GHG emissions from the trucks when transporting the raw materials/products and loading/dumping the materials at both the job site and the hot mix plant. The operation of the rest of the equipment/vehicles was obtained from the contractor’s daily report in terms of total labor hours.

The emissions associated with materials, to-plant delivery, and in-plant production were estimated through the survey of sixteen hot mix producers from Maryland, Virginia, and Pennsylvania in 2013. The six hot mix producers included in the survey were WMA certified. The average WMA output percentage was 19%. The average percentage of RAP in our survey is 23%, higher than 2011 statistic nationwide average value of 19% reported by NAPA (2013). Higher percentage of RAP implies a more conservative benchmark. In addition, this survey covered typical fuel types for HMA facilities and the proportion of each fuel type approximately represented fuel structure of HMA plants (EPA, 2000). Out of sixteen plants in the survey, ten plants consumed natural gas, three consumed oil, and three consumed propane. This proportion is aligned with the number published by EPA that natural gas fuel is used to produce 70% to 90% of the HMA.

Each producer reported raw material consumption, delivery distance, and fuel use by the rotary dryer plus additional fuels used inside the gate by equipment and vehicles on a quarterly basis in 2013. GHG emission intensity was determined following Equations A1 to A5 below. A calculation example for an individual HMA facility is displayed in Table A1 and a summary result for the sixteen facilities is displayed in Table A2.

Raw material production:

$$EI_M = \frac{EF_M \times W_M}{Project\ amount} \quad \text{(A1)}$$

Where:

EI_M	=	Emission intensity of raw material production (kgCO_2e/t)
EF_M	=	Material emission factor (kgCO_2e/kg)
W_M	=	Material weight (kg)
Project amount	=	Amount of HMA manufactured (t)

Plant production:

$$EI_P = EI_D + EI_E \quad \text{(A2)}$$

Where:

EI_P	=	Emission intensity of in-plant production (kgCO_2e/t)
EI_D	=	Emission intensity of diesel-consuming activities (kgCO_2e/t)
EI_E	=	Emission intensity of electricity-consuming activities (kgCO_2e/t)

$$EI_D = \frac{EF_{EQ} \times HR_{EQ}}{Project\ amount} \quad \text{(A3)}$$

Where:

EI_D	=	Emission intensity of diesel-consuming activities (kgCO_2e/t)
EF_{EQ}	=	Equipment emission factor (kgCO_2e/hour)
HR_{EQ}	=	Equipment operation hours (hour)
Project amount	=	Amount of HMA manufactured (t)

$$EI_E = \frac{EF_{EL} \times C_{EL}}{Project\ amount} \quad \text{(A4)}$$

Where:

EI_E	=	Emission intensity of electricity-consuming activities (kgCO_2e/t)
EF_{EL}	=	Electricity emission factor (kgCO_2e/kWh)
C_{EL}	=	Electricity consumption (kWh)
Project amount	=	Amount of HMA manufactured (t)

Raw material delivery:

$$EI_{PD} = \frac{Distance_P \times EF_T}{Project\ amount} \quad \text{(A5)}$$

Where:

EI_{PD}	=	Emission intensity of to-plant delivery ($kgCO_2e/t$)
$Distance_P$	=	Distance to plant (mile)
EF_T	=	Truck emission factor ($kgCO_2e$/mile)
Project amount	=	Amount of HMA manufactured (t)

Table A1: Example Calculation of GHG Emissions from Hot Mix Facility

HMA Plant 1	Operation period: 7/1/2013 to 9/30/2013

The emissions associated with to-site delivery and on-site installation were estimated through the survey of patching and roadway projects. Ten HMA patching projects were surveyed to calculate baseline emissions for patching projects. For each project, the operation information for trucks, which deliver the hot mix to the job site and carry the RAP from the job site to the central plant, was obtained from truck driver reports. The truck driver reports recorded the time in and out from the job site for each truck, total mileage travelled, and gallons of diesel used by each truck. The recorded information was then used for estimating the GHG emissions from the trucks when transporting the recycled materials/products and loading/dumping the materials at both the job site and the central plant. The operation of the rest of the equipment/vehicles was obtained from the contractor’s daily report in terms of total labor hours.

Three out of ten projects were selected for a manual assessment of the utilization rate of each individual piece of equipment[7]. The percentage utilization (PU) was calculated using the effective operation time divided by the total labor hours. The average *PU* values are 0.55 for the asphalt-milling machine; 0.10 for the backhoe; 0.10 for the bobcat/loader; 0.4 for the sweeper/broom; 0.10 for the excavator; 0.33 for the paver and 0.45 for the roller. Different equipment utilization levels will produce different amounts of GHG emissions. According to a study by Lewis et al. (2009), the emission rate of idling equipment is about one quarter of the emission rate of the operating equipment. This difference was simplified and incorporated into the emission calculation as an average conversion factor (CF), which equals *PU+0.25(1-PU)*. Calculation equations for equipment emissions during on-site installation are provided below, and the estimation results are displayed in Table A3.

The on-site installation EI (EI_I) is calculated as follows:

$$EI_I = \frac{EF_{EQ} \times HR_{EQ}}{Project\ amount} \quad (A6)$$

Where:

EI_I	=	Emission intensity of pavement installation ($kgCO_2e/t$)
EF_{EQ}	=	Equipment emission factor ($kgCO_2e/hour$)
HR_{EQ}	=	Equipment operation hours (hour)
Project amount	=	Amount of HMA installed (t)

$$HR_{EQ} = HR_{LA} \times CF \quad (A7)$$

Where:

HR_{EQ}	=	Equipment operation hours (hour)
HR_{LA}	=	Labor hours (hour)
CF	=	Conversion factor

Baseline emissions for roadways are generated from the Project Emission Estimator (PE-2). PE-2 collected and organized construction and rehabilitation data from 11 Michigan Department of Transportation HMA pavement, re-construction, rehabilitation, and maintenance projects throughout the State of Michigan in 2011. The amount of GHG emissions from each project is summarized in Table A4.

Results show that the emissions from the hot mix facility and its upstream raw material production range from 59.4$kgCO_2e/t$ HMA to 111.9$kgCO_2e/t$ HMA with an average value of 86.1$kgCO_2e/t$ HMA; the emissions from HMA installation in patching projects range from 42.7 $kgCO_2e/t$ to 135.2 $kgCO_2e/t$ with an average value of 64.6 $kgCO_2e/t$; the emissions from HMA installation projects performed on roadways range from 4.5 $kgCO_2e/t$ to 145.1 $kgCO_2e/t$ with an average value of 55.7 $kgCO_2e/t$.

[7] The patch work was located at the Howard Crossing Apartment, Ellicott City, MD. The sizes of the three patches were 884 square feet, 6,969 square feet and 10,080 square feet.

- US-41 Road Reconstruction HMA and Concrete, 4.4 lane miles

Determination of Performance Benchmark for Additionality and Crediting Baseline

Once the baseline emissions were determined based on a sample of HMA producers and projects were surveyed to represent the sectoral emission performance, this estimation was then applied to determine the performance benchmark which is the same for both additionality and the crediting baseline.

Due to the significant impact of project type and delivery distance on the total amount of GHG emissions, performance benchmarks are proposed for specific project types and the one-way distances between a HMA plant and a job site. Out of a total of ten surveyed projects, six have a hauling distance of less than 40 miles, while four have a hauling distance of greater than 40 miles. Combined with sixteen facilities, the total sampling points were 96 (=16×6) for HMA projects (< 40mi) and 64 (=16×4) for HMA projects (>40mi). The combination covers all the possible values of emission intensities of the sampled projects. Statistical analysis of the sampling population shows that when the distance is less than 40 miles, the average baseline emission (μ) is 134.8 kgCO_2e/t HMA and the standard deviation (σ) is 15.5 kgCO_2e/t HMA, as represented in Figure A1 below. When the distance is larger than 40 miles, the average baseline emission (μ) is 170.3 kgCO_2e/t HMA and the standard deviation (σ) is 33.6 kgCO_2e/t HMA. According to UNFCCC (2006), performance benchmarks may be defined as an emission level that is exceeded by 80% of existing HMA projects. Given the sampled projects approximate a normal distribution, the performance benchmark must be 121.9 kgCO_2e/t HMA (equals to μ- 0.84σ) for HMA projects (< 40mi), which is illustrated in Figure A1. The calculation follows a standard cumulative distribution function using normal distribution mean and standard deviation. The performance benchmark is 142.4 kgCO_2e/t HMA for HMA projects (>40mi) as calculated as follows:

Performance benchmark = Average baseline emission – 0.84 × Standard deviation (A9)

For roadway projects, the average baseline emission (μ) is 141.8 kgCO_2e/t HMA and the standard deviation (σ) is 56.2 kgCO_2e/t HMA., and therefore the performance benchmark of roadway projects is 95.1kgCO_2e/t HMA.

APPENDIX C: EXPERT REVIEW PANEL FOR PERFORMANCE BENCHMARKS

Expert Review Panel

An expert panel met on June 23, 2014 at the University of Maryland to review and provide feedback on the levels of performance benchmarks. Experts in attendance included the following:

- Tuncer Edil – Professor Emeritus, Geological Engineering and Civil & Environmental Engineering, University of Wisconsin-Madison
- Gerardo Flintsch – Professor of Civil and Environmental Engineering, Virginia Polytechnic Institute
- Jeff Graf – Executive Vice President, Maryland Paving Inc.
- Luke Wisniewski – Chief Climate Change, Maryland Department of Environment

Other Participants

Other participants included the following:

- Harold Green, GRR
- Dan Shaw, GRR
- Chandra Akisetty PE, GRR
- Qingbin Cui, University of Maryland
- Xiaoyu Liu, University of Maryland
- Sara Berman, Straughan Environmental
- Deborah Sward, Straughan Environmental
- Andrew Beauchamp, Verra
- John Holler, Verra

The meeting included introductions from members of the team, Verra staff, and a summary of the methodology development process. The Expert Review Panel members then asked questions, provided their feedback, and had a discussion with the methodology development team. The following is a summary of the discussion.

Expert Review Panel Discussion

Q1 Luke Wisniewski: Does the use of a thicker base cause any issues matching it to existing roads or cause logistical issues?

Response: No, usually when doing a road rehabilitation –milling out the existing pavement and constructing foam and hot mix—a project will have to mill out an inch deeper in order to compensate for the use of the FSB. If a project is removing 4” of HMA base for replacement with a 5” thick FSB layer, the road will be milled down further to compensate. It also depends on how and where the project occurs and the restrictions and specifications on the grade. If the grade is not to be changed the road will be milled deeper. If the grades can be changed, a transition will be made between the existing pavement and the sections with a layer of FSB. Each project will specify whether the grades need to match or a transition can be made.

Q2 Gerardo Flintsch: The structural layer coefficient of bitumen for cold mix being used is 0.32. Where did this value come from? Please provide further references, and I have a reference I can add (shared with the team through email).

Response: The methodology is being revised to clearly identify how the structural coefficient of 0.32 was developed. The value came from a study conducted by the University of Maryland (UMD) for the Maryland State Highway Administration (MD SHA). UMD collected core samples and had them tested at a lab. The Team conducted some falling weight deflectometer (FWD) tests to determine the resilient modulus (M_r). From the core samples tested and the FWD test the team calculated the layer coefficient. The results of the structural layer coefficient from the samples ranged from 0.38 to 0.4. The Team also conducted a Nomograph test following the Wirtgen Core Recycling Mix Manual and examined the values for the asphalt cold mix. Comparing the results allowed for a broader data source to review. In order to be more conservative in our value and to accurately represent all conditions, the team averaged the results from studies conducted throughout the world and developed 0.32 as the structural layer coefficient.

A clarification to the methodology will be made to clearly identify that FSB uses only 1.5-2% more material per cubic foot than HMA. This is because the densities are different. The density for HMA is 160 lbs per cubic ft and for FSB it is 130 lbs per cubic ft. FSB’s layer coefficient is lower than HMA, thus requiring 25% more volume while only requiring 1.5-2% more material to maintain the required specification layer coefficient. The differences between volume and weight will be clarified further within the methodology for calculating emission savings.

The methodology team will include further references supporting the methodology findings. A report by Charles Schwartz (team member) and Sadaf Khosravifar for “State Highway Administration Research Report: Design and Evaluation of Foamed Asphalt Base Materials” outlines the role of FSB.

Q3 Gerardo Flintsch: One discussion in a lifecycle assessment (LCA) is how do we address the physical stock energy of the asphalt binder? The LCA can be very high. How does the team address this?

Response: The comment is being considered and taken into account in the methodology. Materials emissions factors are coming from Environmental Protection Agency’s database Department of Energy’s, EIO-LCA and other databases publicly available and referenced in the methodology. The equipment emission factors are coming from EPA tier emission standards, and the assembly emission factors come from the Inventory of Carbon and Energy developed by University of Bath, UK. This reference provides material emission factors.

Q4 Tuncer Edil: Considering the maintenance stage produces a considerable amount of emissions, it is important to include this stage in the project boundary. The difference between HMA, CCPR CIR has a high impact on GHG emission levels and the choice of maintenance regime can extend the service life of a road thus considerably reducing GHG emissions over its lifespan.

Response: Maintenance was not included within the project boundary given the great variability of road maintenance requirements due to geographic location and ownership protocol. LCA can take a cradle to grave or a cradle to gate approach. The team decided on a cradle to gate in order to reduce potential variability of GHG emissions due to the broad range of road maintenance schedules/strategies over the 50 year lifespan of a road. Including maintenance over a 50-year period will in turn skew the calculation due to the significant amount of emissions associated with a project boundary of 50 years. 50 years would also prove difficult to monitor for a project boundary. The current project boundary meets with ISO standards and guidance. The initial designs have considered the differences between structural layer coefficients of two materials – 4 inch base using HMA and 5 inch base using FSB. The structural performance must be the same when road is constructed (or reconstructed) using the two materials. The maintenance schedule can be reasonably assumed to be same frequency and activity, accordingly.

Q5 Tuncer Edil: Is the service life of FSB the same as HMA?

Response: The service life of FSB and HMA are similar. FSB is used as base a layer with HMA as a surface layer. Under this circumstance the service life is dictated by HMA surface layer performance. The performance of roads with and without FSB as a base layer are very similar. The structural integrity was found to be the same by Schwartz & Khosravifar. The National Center for Asphalt Technology (NCAT) in their Spring 2014 (Volume 26 Number 1) report evaluates structural integrity and maintenance over a two-year period. They have completed 80% of the study. The results to date have been positive with10 million Equivalent Single Axle Load (ESALs) with no significant cracking or rutting reported in the interim report.

Q6 Gerardo Flintsch: The methodology reference data from 2002. There has been much development in the construction equipment manufacturing industry. Equipment used in manufacturing has become efficient over the past 12 years reducing GHG emissions level. However the research studies referenced date back to 2002 for EIO-LCA. However, the HMA equipment data is from 2009. Why do you continue to use data from 2002?

Response: The 2002 data is for the materials side. The 2002 data used in the model comes from the Department of Commerce. The current version of the model they developed is based on 2002 data. The team will confirm and provide further documentation within the methodology to explain why the methodology includes data from 2002.

Q7 Sara Berman: Does the Additionality threshold accurately represent the industry? Does the expert review panel believe there to be false negatives or false positives within the threshold? Is the threshold too stringent or too lenient?

Response from team: The team averaged data from HMA plants surveyed throughout MD and VA. 80% was a threshold found throughout other methodologies. Taking the survey of HMA plants conducted by the team into account and the 80% threshold used by other methodologies made sense given the industry.

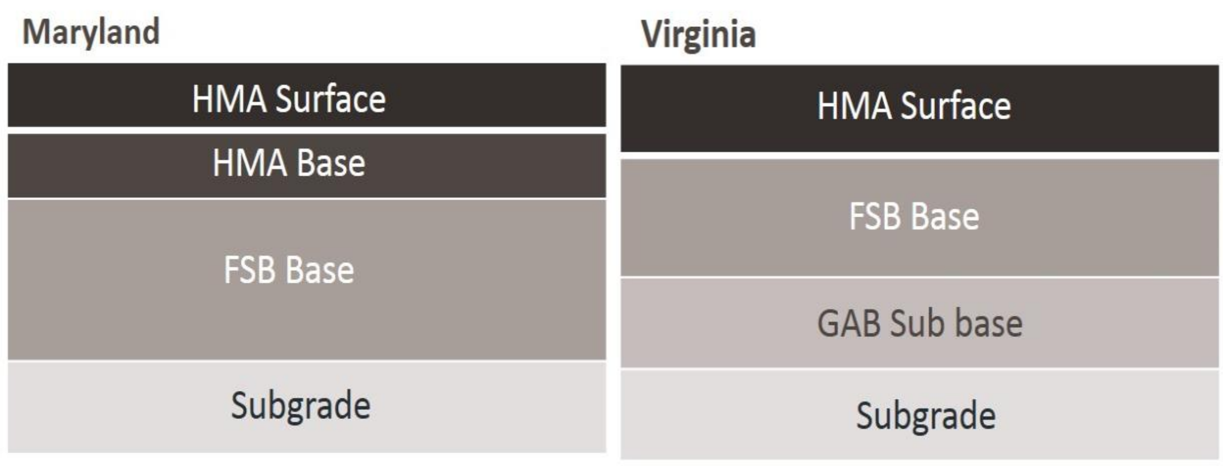
Q8 Sara Berman: Luke Wisniewski do you think there is sufficient regulatory support and/or guidance, which will allow for a market for the methodology to move forward? Could MDE support this moving forward from a regulatory standpoint?

Luke Wisniewski: There is sufficient information for the methodology to move forward. The protocol would have to be validated by an independent organization. If there is a market for offsets it can move forward. MDE will accept the use of FSB. MDE can accept it as the protocol or as an offset credit if it is approved and used appropriately.

Q9 Sara Berman: How significant is the difference between the Maryland and Virginia specifications for the use of FSB in road construction?

Response: There is a considerable difference between Maryland and Virginia FSB use specifications. The following diagram outlines the two specifications. It is important to note the use and location of FSB in relation to the other materials.

Figure C1: FSB Specification for Maryland and Virginia



Q10 Sara Berman: Are there financial incentives to use FSB?

Response: Presently, there are no financial incentives to use FSB rather than HMA.

Q11 Sara Berman: Is there a rationale for why the experts support the methodology?

Response: Tuncer Edil finds that once the team addresses the comments from this meeting the methodology will be ready to move forward. Other reviewers support the methodology moving forward.

Q12 Tuncer Edil: There has been much improvement in incorporating RAP and RAS in recent years into HMA mix designs. The methodology references 3% RAS in the HMA mix, which is surprisingly low. On page 25 change 2006 to 2010 in footnote 3.

Response: The usage of 3% RAS was found to be representative of the HMA plants surveyed in the development of the methodology. The methodology will provide further documentation supporting the use of 3% and include an additional footnote for clarification.

Q14 Gerardo Flintsch: Although the methodology is focused on FSB, emulsion is included in several places. Is emulsion going to be considered? If so, emulsion needs further clarification and documentation. Will this impact the structural layer coefficient?

Response: Emulsion will be included in the methodology. It is a similar process to foam. The difference between foam and emulsion is when the mix occurs. The methodology will be adapted to accurately represent this in the methodology. The model will address emulsion moving forward.

Questions from Jeff Graf

Jeff Graf was unable to attend the meeting. His comments and questions with the team response are listed below.

Q1: Jeff would like the group to take into account the nascent industry trend of using warm mix rather than hot mix. Warm mix allows roads to cool faster in warmer climates, and thus enables roads to open sooner to traffic and shorten project time. This would alter the baseline and change the overall accounting of GHG savings.

Response: Warm-mix is an upcoming technology and we have used warm-mix data from various plants in our calculations. Our data points include warm mix data from HMA plants and the corresponding GHG response includes warm-mix.

Q2: Jeff asked why the boundary was set as cradle-to-gate rather than cradle to grave. He believes we need to identify that in the use of the RAP the ownership remains with the construction of the road and not with the individual who ground up the road for a CCPR project.

Response: The boundary setting was discussed earlier in the report in order to feasibly observe the project lifespan and eliminate broad variability of road maintenance schedules, which are geographically specific.

Q3: Jeff indicated that CIR projects are often based on the space available to stage the project and size of project area being resurfaced. He recommends further clarification within the methodology as to when CIR projects are feasible.

Response: Three types of recycling methods are being used in pavement industry. First HIR (hot in-place recycling), which is feasible for only top 2 inches of HMA pavement. Second CCPR (cold central plant recycling), which is feasible if the HMA pavement is cracked and rutted up to 4 to 6 inches. Last one is CIR (cold in-place recycling), which is generally preferable if the pavement has to be rehabilitated until the top one inch of base course (severely cracked and rutted pavements up to 4 to 12 inches). The choice of which type to apply is dependent on the area where the recycling project is located and existing drainage conditions of the pavement and economic feasibility. Some projects without proper drainage or existing paving fabric or poor base course condition are not suitable for CIR projects, even if it is economical to do so. It will then have to be replaced with CCPR process.

Q4: Was Maryland Department of Environment's AP 42 referenced for emissions calculations?

The Economic Input-Output LCA Model was adopted to calculate material GHG emissions, which was developed by Carnegie Mellon University. The EPA engine certification database was adopted to calculate equipment GHG emissions. We used nationwide emission factor database, as opposed to state-specific emission factor database.

Q5: The methodology mentions cement in the FSB mix. Is this used across the board? Does it vary based on different State Planning and Research offices (SPR)? With new construction will you have to add more cement to the mix in order for it to adhere properly?

Response: Cement is added in FSB mixes, because it helps to increase the moisture susceptibility resistance. Each project will comply with SPR, project requirements based on specifications and road conditions.

Q6: On a new construction project using FSB, will additional binder or cement be needed to achieve the structural integrity required? If so, will this impact your calculations?

Response: No additional binder or cement is required for new projects. For either new projects or rehabilitation projects, the project team will collect the RAP samples from stockpiles or job sites respectively and develop mix design in the laboratory. Usually the binder content requires varies between 2.1% to 2.3% and cement content always stays at 1%. Portland cement helps the mix to increase the moisture susceptibility resistance and increase its wet ITS (indirect tensile strength) value in FSB mix. It also helps to add extra fines, which are required very often in RAP samples to absorb the expanded asphalt binder. If the cement content increases, the mix loses flexibility and it will become counterproductive.

Methodology for Greenhouse Gas Capture and Utilization in Plastic Materials

Version 1.0

23 July 2019

Sectoral Scope 3

This methodology was developed by:

Newlight Technologies

TABLE OF CONTENTS

1 SOURCES

This methodology was informed primarily by CDM methodology AMS-III.BA, *Recovery and recycling of materials from E-Waste*, particularly the principle of using recycled materials to displace virgin materials production.

2 SUMMARY DESCRIPTION OF THE METHODOLOGY

This methodology is globally applicable to project activities that convert carbon dioxide and/or methane, which would have otherwise been emitted into the atmosphere, into a useful plastic material for sale into the plastics market. Such project activities reduce greenhouse gas emissions in two ways. First, project activities sequester carbon dioxide and/or methane into plastic material. Second, the process for manufacturing plastic material from sequestered carbon dioxide and/or methane can be less emission-intensive than the traditional process for manufacturing plastic material.

Additionality and Crediting Method	
Additionality	Activity Method
Crediting Baseline	Project Method

3 DEFINITIONS

In addition to the definitions set out in VCS document *Program Definitions*, the following definitions apply to this methodology:

Additives
Materials that are added in the middle of the production process to provide certain qualities or attributes to the final product. The incorporation of additives must be considered and accounted for when quantifying the total amount of GHG feedstocks used in the final product.

Biodegradable
A material that will decompose in less than 100 years due to the activity of bacteria or other living organisms

DMM (Direct Measurement Method)
The direct measurement method is a method used to calculate the amount of GHGs sequestered into plastic materials. It uses volumetric or mass-flow meters to measure the GHG input as it enters the production process.

Feedstock
The greenhouse gases (i.e., CO_2 and/or CH_4) which are captured as part of project activities to be used along with other materials to produce plastic material

MFR (Molecular Formula Ratio)
The Molecular Formula Ratio is a method used to calculate the amount of GHGs sequestered into plastic materials. It refers to the stoichiometric ratio method, which calculates the quantity of GHGs sequestered based on the chemical formula and weight of the final plastic material.

Non-Qualifying CH_4
Methane which is part of the GHG feedstock, but which would have been captured and destroyed in the baseline scenario (e.g., via a landfill collection system)

Plastic Material
Resins or pelletized material that can be molded into useful products. These materials directly displace conventional plastics such as polypropylene (PP), polystyrene (PS), polyethylene (PE), thermoplastic urethane (TPU), acrylonitrile butadiene styrene (ABS), polycarbonate (PC) and polyethylene terephthalate (PET).

Qualifying CH_4
Methane which is part of the GHG feedstock that would have been emitted into the atmosphere in the baseline scenario

Thermopolymer
Also known as thermoplastic polymers, which form when repeating units called monomers link into chains or branches. Because they soften when heated, thermoplastic polymers are easy to mold into a variety of shapes.

Virgin plastic
Plastic material that is manufactured for the first time and used in products that the project activity would be displacing. Virgin plastic is typically made from petroleum-based materials.

4 APPLICABILITY CONDITIONS

This methodology is globally applicable to project activities that convert carbon dioxide and/or methane, which would have otherwise been emitted into the atmosphere, into a useful plastic material for sale into the plastics market.

Project activities must meet the following conditions:

1) Project activities must produce a useful plastic material through a carbon capture and utilization technology which converts CO_2 and/or CH_4 into a long-chain thermopolymer. Such plastic material must:

    a) Have an expected lifetime (period of non-degradation) of at least 100 years[1], or

    b) Be biodegradable. However, in such cases the project may only calculate emission reductions related to the displacement of virgin plastic, and must NOT account for the

[1] Plastic materials produced by projects must permanently sequester carbon (i.e., sequester carbon for a period of at least 100 years) in order to claim emission reductions for the capture and sequestration of GHGs. Many plastic materials are well-known to have degradation times significantly greater than 100 years. Please refer to the following articles, which are cited in Section 10 of this methodology: Andrady (2003); Barnes et al. (2009); Browne et al. (2007); Thompson et al. (2004); Thompson et al. (2005).

capture and sequestration of GHGs, which would be re-released to the atmosphere in the case of biodegradable materials.

2) Project activities must produce a plastic material that will be used to produce useful plastic products that are sold in the commercial market.

3) Project activities must produce PHA (polyhydroxyalkanoates) directly from CO_2 or CH_4 through a process in which the resultant material displaces one of the following plastic materials:

   - Polypropylene (PP)
   - Polystyrene (PS)
   - Polyethylene (PE), including high-density and low-density polyethylene (HDPE, LDPE) and linear low-density polyethylene (LLDPE)
   - Thermoplastic urethane (TPU)
   - Acrylonitrile butadiene styrene (ABS)
   - Polycarbonate (PC)
   - Polyethylene terephthalate (PET)
   - Polyvinyl Chloride (PVC)

4) Project activities cannot combine CO_2 and CH_4 as feedstock to create a single plastic material.

5) Where CO_2 is used as a feedstock, it must be derived from a source that would have otherwise emitted it to the atmosphere (i.e., the CO_2 is not processed/produced specifically for this project activity) or it must be derived from direct air capture technology.

6) Where CH_4 is used as feedstock, the project proponent must demonstrate whether the CH_4 is qualifying or non-qualifying, as further defined in Section 8.3 below.

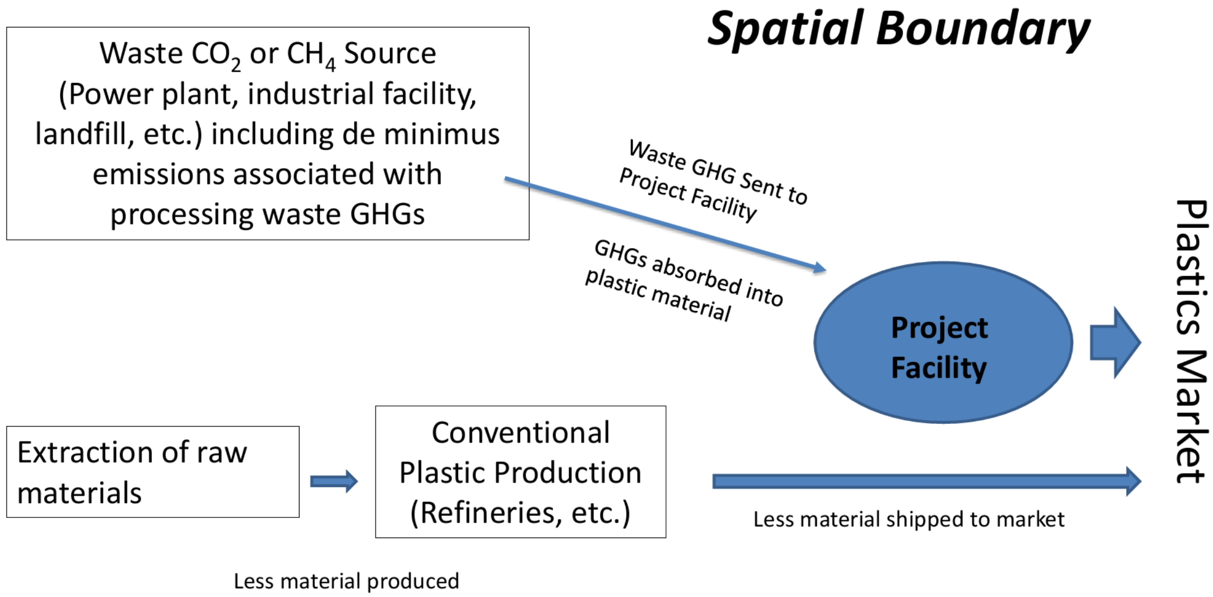
7) Where CH_4 is used as feedstock, the CH_4 used in the project activity cannot be displaced by a more carbon-intensive fuel, as demonstrated by meeting one or more of the conditions set out in Section 8.3 below.

5 PROJECT BOUNDARY

As illustrated below, the spatial extent of the project boundary encompasses:

- The project facility where plastic materials are produced;
- The facilities from which the GHG feedstock is sourced (if not direct air capture);
- The facilities where displaced conventional plastic material is manufactured.

Figure 1. Spatial Boundary of the Project Activity



The greenhouse gases included in or excluded from the project boundary are shown in Table 1 below.

Table 1: GHG Sources Included In or Excluded From the Project Boundary

Source		Gas	Included?	Justification/Explanation
Baseline	Captured GHGs	CO_2	Optional	CO_2 is one of the main gases that can be captured by carbon capture and utilization technology. Note that some projects may use only CH_4 and not CO_2, in which case CO_2 may be excluded from the project boundary. Either CO_2 and/or CH_4 must be included within the project boundary.
		CH_4	Optional	CH_4 is one of the main gases that can be captured by carbon capture and utilization technology. Note that some projects may use only CO_2 and not CH_4, in which case CH_4 may be excluded from the project boundary. Either CO_2 and/or CH_4 must be included within the project boundary.
		N_2O	No	N_2O and any other GHGs are not gases that would be captured and utilized in plastic material with current technology.
		Other	No	N/A
	GHGs from displacement of traditional	CO_2	Yes	The use and combustion of fossil fuels is the primary source of emissions from the traditional process of manufacturing plastics,

Source		Gas	Included?	Justification/Explanation
	plastics production			including the refining of raw materials and process energy for production of plastics. See Appendix II for further detail. Note – transportation of plastic materials is not considered in either the baseline or project scenario because it is assumed that under either scenario, conventional plastics or GHG-captured plastics would require similar means of transport.
		CH_4	No	Excluded for simplicity
		N_2O	No	Excluded for simplicity
		Other	No	N/A
Project	GHGs from the project facility	CO_2	Yes	Use of electricity and combusted natural gas or liquid/solid fuels are the primary energy sources that would be used to power a facility capturing GHGs and manufacturing plastic material, and thus CO_2 would be the primary emission from that combustion.
		CH_4	No	Excluded for simplicity
		N_2O	No	Excluded for simplicity
		Other	No	Excluded for simplicity
	GHGs from burning of plastic material that previously captured and sequestered CO_2 and CH_4	CO_2	Yes	Incineration of plastic material, re-releasing CO_2 into the atmosphere
		CH_4	No	Excluded for simplicity
		N_2O	No	Excluded for simplicity
		Other	No	Excluded for simplicity
	Upstream emissions associated with processing waste GHGs	CO_2	No	Excluded since project upstream emissions are negligible compared to the baseline upstream emissions associated with traditional plastic production.
		CH_4	No	
		N_2O	No	
		Other	No	

6 BASELINE SCENARIO

The baseline scenario is the continuation of manufacturing plastic material through traditional processes (i.e., not through the use of GHG capture and utilization technology). This methodology uses a project method to determine the crediting baseline.

7 ADDITIONALITY

This methodology uses an activity method for the demonstration of additionality.

Step 1: Regulatory Surplus

Project proponents must demonstrate regulatory surplus in accordance with the rules and requirements regarding regulatory surplus set out in the latest version of the *VCS Standard*.

Step 2: Positive List

The applicability conditions of this methodology represent the positive list. The project must demonstrate that it meets all applicability conditions, and in so doing, it is deemed as complying with the positive list and as being additional.

The positive list was established using the activity penetration option (Option A in the *VCS Standard*). Justification for the activity method is provided in Appendix I.

8 QUANTIFICATION OF GHG EMISSION REDUCTIONS AND REMOVALS

8.1 Baseline Emissions

Emissions in the baseline scenario are comprised of two components. The first component is the emissions associated with traditional plastic materials production processes. The second component is the emissions from the GHG feedstock which would remain in the atmosphere or be released to the atmosphere in the absence of the project.

Component 1: Plastic production

Emissions associated with the production of virgin plastic through traditional processes that are displaced by the plastic material manufactured by the project must be accounted for in the baseline scenario. Appendix II provides default factors for GHG emissions per metric ton of virgin or new plastic (note that virgin plastic may have some recycled plastic as indicated in Appendix II, Table 3b) produced using traditional plastic production processes for different types of plastic materials. It may be assumed that for every metric ton of plastic material manufactured at a project facility, a metric ton of plastic material produced through traditional processes is displaced.

Component 2: GHG feedstock

Where the project captures CO_2 from flue gases to produce plastics, CO_2 emissions in the baseline scenario are simply those that would otherwise be released to the atmosphere.

Where the project uses CH_4 as feedstock for plastic production, the CH_4 may be derived from two types of sources:

1) **Non-qualifying CH_4:** Methane that comes from a landfill or other source where it is required to be flared or otherwise destroyed in the baseline scenario. Where non-qualifying CH_4 is captured as part of project activities, emissions in the baseline scenario must only be attributed to the CO_2 that is released as a result of the CH_4 flaring or destruction process.

2) **Qualifying CH_4:** Methane that comes from a source where it is not required to be flared or otherwise destroyed in the baseline scenario (e.g., a small landfill or biogas facility). Where qualifying CH_4 is captured as part of project activities, emissions in the baseline scenario are attributed to the release of such CH_4 to the atmosphere.

Baseline emissions in year *y* of the project crediting period (BE_y) is therefore expressed as follows:

$$BE_y = BE_{tp,y} + BE_{cg,y} \quad (1)$$

Where:

BE_y	= Baseline emissions in year y
$BE_{tp,y}$	= Baseline emissions from plastic material production via traditional manufacturing processes (tCO_2e) in time period *y*
$BE_{cg,y}$	= Baseline emissions from the GHG feedstock which would remain in, or be released to, the atmosphere in the absence of the project (tCO_2e) in time period *y*

Baseline emissions from plastic material production via traditional manufacturing processes is calculated as follows:

$$BE_{tp,y} = \sum_i (Q_{p,i,y} * EF_i) \quad (2)$$

Where:

$BE_{tp,y}$	= Baseline emissions from plastic material production via traditional manufacturing processes (tCO_2e) in time period *y*
$Q_{p,i,y}$	= Net quantity of plastic type *i* produced by the project in year *y* (metric ton)
EF_i	= Emission factor associated with the production of virgin plastic materials via traditional manufacturing processes (tCO_2e/metric ton of plastic for plastic type *i*)

The net quantity of plastic type *i* produced by the project in year *y* ($Q_{p,i,y}$) is calculated as follows:

$$Q_{p,i,y} = Q_{gross,i,y} - Q_{add,i,y} \quad (3)$$

Where:

$Q_{p,i,y}$	= Net quantity of plastic type *i* produced by the project in year *y* (metric ton)
$Q_{gross,i,y}$	= Gross quantity of plastic type *i* produced by the project in year *y* (metric tons)

$Q_{add,i,y\ i}$ = Quantity (mass) of any additives or supplemental material that may be added to the plastic resin for plastic type *i* produced by the project in year *y* (metric tons)

Guidance regarding the calculation of EF_i is given in the parameter tables in Section 9.1 and further details for the calculation of the default values for EF_i can be found in Appendix II. Different types of plastic material have different emission factors, and therefore, where a project produces more than one type of plastic material, the emissions from each type of plastic material must be calculated separately, and then summed.

Baseline emissions from the GHG feedstock which would remain in, or be released to, the atmosphere in the absence of the project is calculated as follows:

$$BE_{cg,y} = Q_{CO2.seq,y} + Q_{CH4.ADJ,y} \qquad (4)$$

Where :

$BE_{cg,y}$ = Baseline emissions from the sequestration of GHGs into plastic materials

$Q_{CO2,seq,y}$ = Amount of CO_2 captured in year *y* to produce plastic material *i* by the project (metric tons per year)

$Q_{CH4,ADJ,y}$ = Adjusted amount of CH_4 captured in year *y* to produce plastic material *i* by the project (metric tons per year)

Note – Where the plastic produced by the project activity is biodegradable, then it is assumed that all quantities of GHGs captured will eventually be released, in which case $BE_{cg,y} = 0$.

$Q_{CO2,seq,y}$ and $Q_{CH4,ADJ,y}$ must be determined using the molecular formula ratio (MFR), which determines the quantity of CO_2 or CH_4 captured, based on the molecular formula of the final plastic material. For each type of plastic *i*, the project proponent must provide the molecular formula, as well as the formula for the conversion from the GHGs which convert to the plastic material. An example of how to determine the MFR is provided in Appendix III.

Where CO_2 is used as a feedstock, the quantity of CO_2 sequestered is calculated as follows:

$$Q_{CO2.seq,y} = \sum_i \{[Q_{p,i,y} * (MW_C / MW_{p,i})] / RCM_{CO2}\} \qquad (5)$$

Where:

$Q_{CO2,seq,y}$ = Amount of CO_2 captured in year *y* to produce plastic material *i* by the project (metric tons per year)

$Q_{p,i,y}$ = Net quantity of plastic type *i* produced by the project in year *y* (metric ton)

MW_C = Molecular weight of the carbon in the plastic material *i* (g/mol)

$MW_{p,i}$ = Total molecular weight of the plastic material *i* (g/mol)

RCM_{CO2} = Fraction of carbon as part of the carbon dioxide molecule (% carbon in carbon dioxide by molar weight or 27.27%)

Where CH_4 is used as a feedstock, the quantity of CH_4 sequestered is calculated as follows:

$$Q_{CH4.seq,y} = \sum_i [Q_{p,i,y} * (MW_{C,CH4} / MW_{p,i})] / RCM_{CH4} \quad (6)$$

Where:

$Q_{CH4,seq,y}$ = Amount of CH_4 captured in year *y* to produce plastic material *i* by the project (metric tons per year)

$Q_{p,i,y}$ = Net quantity of plastic type *i* produced by the project in year *y* (metric ton)

$MW_{C,CH4}$ = Molecular weight of the total number of carbon molecules in the plastic material *i* (g/mol)

$MW_{p,i}$ = Total molecular weight of the plastic material *i* (g/mol)

RCM_{CH4} = Fraction of carbon as part of the methane molecule (% carbon in methane by molar weight, or 75%[2])

Where CH_4 is used as a feedstock, adjustments must be made because some of the CH_4 may be non-qualifying, as follows:

$$Q_{CH4.ADJ,y} = (Q_{CH4.seq,y} * GWP_{CH4} * QF_{Per,y}) + [Q_{CH4.seq,y} * 44/16 * (1-QF_{Per,y})] \quad (7)$$

Where:

$Q_{CH4,ADJ,y}$ = Adjusted amount of CH_4 captured in year *y* to produce plastic material *i* by the project (tCO_2e per year)[3]

$Q_{CH4.seq,y}$ = Amount of CH_4 captured in year *y* to produce plastic material *i* by the project (metric tons per year)

GWP_{CH4} = Global warming potential of methane

$QF_{Per,y}$ = Percentage of methane captured that is qualifying methane

44/16 = Ratio of the molecular weight of CO_2 to CH_4

[2] Carbon (12) + 4 hydrogen (4) = a molecular weight of 16 g/mol. And 12/16 = 75%

[3] Note that the quantity of any GHG captured in the process must be measured at the very point in which the GHGs are sequestered. In other words, in a multi-step process, GHGs may be captured but some may escape throughout each stage of the process. The meter for captured GHGs should be at the point where as much of the GHGs will be captured as possible.

Projects cannot combine CO_2 and CH_4 as feedstock.[4]

In addition to determining the weight from the molecular formulas, a cross-check must be applied based on the direct monitoring of GHG capture[5]. In this case, directly monitoring the amount of CO_2 and CH_4 going into the process will provide validation of the left side (input) of the molecular formula (the direct measurement method (DMM)). The equation to use for the cross-check is as follows:

$$Q_{GHG,seq,check,y} = Q_{CO2,meter,y} + Q_{CH4,meter,y} \quad (8)$$

Where:

$Q_{GHG,seq,check,y}$	= The cross check of $Q_{CO2,seq,y}$ and $Q_{CH4,ADJ,y.}$ (metric tons)
$Q_{CO2,meter,y}$	= Amount of CO_2 captured in year *y* to produce plastic material by the project, as determined by a flow meter (metric tons)[6]
$Q_{CH4,meter,y}$	= Amount of CH_4 captured in year *y* and used to produce long-lived plastic products (metric tons)

Note that $Q_{CO2,seq,y}$ and $Q_{CH4,ADJ,y}$ will be the variables actually used for baseline emission calculations (metric tons of GHG/year), unless $Q_{GHG,seq,check,y} < Q_{CO2.seq,y} + Q_{CH4.seq,y}$. Where $Q_{GHG,seq,check,y} < Q_{CO2.seq,y} + Q_{CH4.seq,y}$, an explanation and correction must be provided. Where no reasonable explanation or correction can be provided, then the lower, metered values must be used in order to be conservative (i.e., $Q_{CO2.seq,y} = Q_{CO2,meter,y}$ and $Q_{CH4.seq,y} = Q_{CH4,meter,y}$).

8.2 Project Emissions

Project emissions include emissions from electricity use and fossil fuel combustion at the project production facility, and emissions from the amount of plastic made by the project activity that is eventually destroyed by incineration.

Project emissions are calculated as follows:

$$PE_y = PE_{inc,y} + PE_{elec,y} + PE_{ffc,y} \quad (9)$$

---

[4] CO_2 and CH_4 cannot be combined together to form a single plastic material because determining the source of the carbon atom in the molecular formula of the plastic, and whether it came from CO_2 or CH_4 would be difficult. A project may use both CO_2 and CH_4 to produce different plastic materials, but there must always be separate reactions each using *either* CO_2 *or* CH_4 or as a feedstock.

[5] Determining GHG input by direct measurement is intended to be used as a validation of the molecular formula ratio because a validation/verification body (VVB) cannot directly measure or test the exact molecular formula of the plastic resin. Because no process is 100% efficient, it would be expected that some GHGs that enter the process are lost at some point before the final plastic is produced. Thus, the measurements of GHGs via the meter should be greater than what is determined to be sequestered into the plastic through the molecular formula ratio for $Q_{p,i,y}$. Thus, where the meter measurements are less than what is determined via the molecular formula ratio, an explanation or corrective action would need to be provided by the project proponent. Where no explanation or correction can be provided by the project proponent, then the project must use the lower, metered values in order to be conservative (i.e., $Q_{CO2.seq,y} = Q_{CO2,meter,y}$ and $Q_{CH4.seq,y} = Q_{CH4,meter,y}$).

[6] Note that the quantity of any GHG captured in the process must be measured at the very point in which the GHGs are sequestered. In other words, in a multi-step process, GHGs may be captured but some may escape throughout each stage of the process. The meter for captured GHGs should be at the point where as much of the GHGs will be captured as possible.

Where:

PE_y	= Project emissions for year *y* of the project crediting period (tCO_2e)
$PE_{inc,y}$	= Project emissions from the eventual incineration of a portion of plastic that sequestered GHGs, which are then re-emitted (tCO_2e)
$PE_{elec,y}$	= Project emissions from the use of electricity at the project production facility (tCO_2e)
$PE_{ffc,y}$	= Project emissions from the combustion of fossil fuels at the project production facility (tCO_2e)

Project emissions from the incineration of plastic are calculated as:

$$PE_{inc,y} = (Q_{CO2.seq,y} * DF_{EL}) + (Q_{CH4.seq,y} * DF_{EL} * 44/16) \quad (10)$$

Where:

$PE_{inc,y}$	= Project emissions from the eventual incineration of a portion of plastic that sequestered GHGs, which are then re-emitted (tCO_2e)
$Q_{CO2,seq,y}$	= Amount of CO_2 captured in year *y* to produce plastic material *i* by the project (metric tons per year)
DF_{EL}	= Discount factor applied for volume of end-of-life plastic material that can be expected to be incinerated, thus releasing the CO_2 or CH_4 that was originally sequestered.
$Q_{CH4,seq,y}$	= Amount of CH_4 captured in year *y* to produce plastic material *i* by the project (metric tons per year)

Further guidance for calculating DF_{EL}, including a default factor for projects located in the United States and a conservative global default factor, are included in the parameter tables in Section 9.1 and in Appendix II, below.

Project emissions from the use of electricity at the project production facility are calculated as:

$$PE_{elec,y} = Q_{elec,y} * EF_{elec} \quad (11)$$

Where:

$PE_{elec,y}$	= Project emissions from the use of electricity at the facility in year *y*
$Q_{elec,y}$	= Quantity of electricity from the grid in year *y* used to power the project production facility in year *y* (MWH)
EF_{elec}	= Emissions intensity of the electricity in tCO_2/MWH.

Project emissions from the combustion of fossil fuels at the project production facility are calculated as follows:

$$PE_{ffc,y} = Q_{ff,y} * FC_y * EF_{a,y} \quad (12)$$

Where:

$PE_{ffc,y}$	= Project emissions from the combustion of fossil fuel in year y
$Q_{ff,y}$	= Quantity of fossil fuel used in year *y*
FC_y	= Energy content of fuel type a combusted the year *y* (terajoule or TJ).
$EF_{a,y}$	= Emission factor of fuel in year *y* (tCO_2e/TJ).

8.3 Leakage

There is one potential source of leakage to consider under this project activity. Specifically, where methane was supplied from a landfill to be used as a feedstock for this project activity in sufficient quantities, it is conceivable that the facility previously using that methane would turn to other, potentially more carbon-intensive fuels as a substitute. In order to deal with this potential issue, the project proponent cannot count for qualifying methane any biogas that was already contracted for by another entity to be used for energy production. As indicated in the applicability conditions of this methodology, where methane is to be used as a feedstock, the project proponent must demonstrate whether the methane is qualifying or non-qualifying (e.g., through a representation with the methane supplier or other evidence to the satisfaction of the validation/verification body (VVB)). In addition, in situations where an existing source of methane is supplying feedstock to the project facility, the project proponent must:

- Demonstrate that the methane for the project is coming from an expansion of the methane source where methane was previously being vented (e.g., a landfill that is expanding its gas collection system). In such case, it can be assured that no methane is being diverted from another fuel use because the ability to collect biogas is being increased; or

- Demonstrate there is excess gas supply potential that is not being utilized by the landfill or other methane source. For example, if projections of gas availability (to be provided by the landfill operator) show gas supply should be higher than what was actually being used, it would indicate that there is *potential* for more biogas to be used than is actually the case; or

- Provide other evidence to the satisfaction of the VVB that the methane source is supplying biogas which is not being diverted to another user.

Where the project proponent can demonstrate that one or more of these conditions exist for the project activity, then leakage does not need to be taken into consideration. Where these conditions cannot be definitively confirmed, the methane provided from the facility cannot count towards baseline emissions.

8.4 Net GHG Emission Reduction and Removals

Net GHG emission reductions and removals are calculated as follows:

$$ER_Y = BE_Y - PE_y \quad (13)$$

Where:

ER_Y = Net GHG emissions reductions and removals in year y (tCO_2e)

BE_Y = Baseline emissions in year y (tCO_2e)

PE_y = Project emissions in year y (tCO_2e)

9 MONITORING

9.1 Data and Parameters Available at Validation

Data / Parameter	EF_i
Data unit	tCO_2e/metric ton of plastic material type i produced
Description	Emission factor for GHG's caused by the production of virgin plastic materials in tCO_2e/metric ton of plastic material
Equations	2
Source of data	Use values from credible international or national government sources, such as the U.S. EPA (see Appendix II, below, for more information on the data used to calculate this variable in the U.S.).
Value applied	See Appendix II
Justification of choice of data or description of measurement methods and procedures applied	National environmental agencies or similar government and research institutions have accurate data on energy requirements for each segment of the plastic production process including raw materials extraction and the production process itself. To be updated each crediting period if new data exists.
Purpose of Data	Calculation of baseline emissions
Comments	N/A

Data / Parameter	MW_C
Data unit	g/mol
Description	Molecular weight of CO_2
Equations	5 and 6
Source of data	Periodic Table of Elements
Value applied	44

Justification of choice of data or description of measurement methods and procedures applied	Molecular weights as provided for in the Periodic Table of Elements.
Purpose of Data	Calculation of baseline emissions
Comments	For each type of plastic *i*, the project proponent must provide the molecular formula, as well as the conversion from the original compounds (including the GHGs) which convert to the plastic material. Taking into account the molecular weight of each compound, the project proponent can then illustrate that for each ton of plastic (eg: $C_4H_6O_2$) produced, X tons of CO_2 are required.

Data / Parameter	$MW_{C,CH4}$
Data unit	g/mol
Description	Molecular weight of CH_4
Equations	5 and 6
Source of data	Periodic Table of Elements
Value applied	16
Justification of choice of data or description of measurement methods and procedures applied	Molecular weights as provided for in the Periodic Table of Elements.
Purpose of Data	Calculation of baseline emissions
Comments	For each type of plastic *i*, the project proponent must provide the molecular formula, as well as the conversion from the original compounds (including the GHGs) which convert to the plastic material. Taking into account the molecular weight of each compound, the project proponent can then illustrate that for each ton of plastic (eg: $C_4H_6O_2$) produced, X tons of CO_2 are required.

Data / Parameter	$MW_{p,i}$
Data unit	g/mol
Description	Molecular weight plastic material
Equations	5 and 6
Source of data	Project proponent must provide formula for plastic material
Value applied	N/A

Justification of choice of data or description of measurement methods and procedures applied	Molecular weights as provided for in the Periodic Table of Elements.
Purpose of Data	Calculation of baseline emissions
Comments	For each type of plastic *i*, the project proponent must provide the molecular formula, as well as the conversion from the original compounds (including the GHGs) which convert to the plastic material. Taking into account the molecular weight of each compound, the project proponent can then illustrate that for each ton of plastic (eg: $C_4H_6O_2$) produced, X tons of CO_2 are required.

Data / Parameter	RCM_{CO2} and RCM_{CH4}
Data unit	Percentage
Description	Fraction of carbon as part of the CH_4 and CO_2 molecule (% carbon in CH_4 and CO_2 by molar weight)
Equations	5 and 6
Source of data	Calculated based on molecular weights of carbon, CO_2 and CH_4.
Value applied	RCM_{CO2} = 27.27% RCM_{CH4} = 75%
Justification of choice of data or description of measurement methods and procedures applied	N/A
Purpose of Data	Calculation of baseline emissions
Comments	N/A

Data / Parameter	GWP of CH_4
Data unit	tCO_2/tCH_4
Description	Global warming potential of methane
Equations	7
Source of data	IPCC
Justification of choice of data or description of measurement methods and procedures applied	The *IPCC Guidelines for National Greenhouse Gas Inventories* are internationally recognized, and the data provided in the guidelines is peer reviewed
Purpose of Data	Calculation of baseline emissions
Comments	N/A

Data / Parameter	DF_{EL}
Data unit	Unitless
Description	Discount factor applied to account for the end of life of plastic material that is incinerated, releasing CO_2
Equations	10
Source of data	U.S. EPA or similar source in other countries (see Appendix II)
Value applied	For projects located in the U.S.: 0.15 For projects located outside of the U.S.: 1) Determine value from credible national government sources (see Appendix II) 2) Global default value: 0.40
Justification of choice of data or description of measurement methods and procedures applied	National environmental agencies or similar government and research institutions have accurate data on the percentage of plastic materials in conventional waste streams and what percentage of those waste stream that is incinerated.
Purpose of Data	Calculation of project emissions – where plastic is incinerated, the captured CO_2 is released, and reductions cannot be credited for this portion of the baseline emissions.
Comments	Discount factor applied to account for the end of life of plastic material that is expected to be incinerated, releasing CO_2. For example, where 20% of plastics in a particular country can be expected to be incinerated instead of recycled or landfilled, then the discount factor is 0.20. To be updated each crediting period if new data exists. Additional Guidance: Projects must apply a discount factor, DF_{EL}, to account for plastics that are destroyed (e.g., through incineration if they enter municipal waste streams), thus releasing the captured CO_2 prior to the end of their lifetime. Accurate data as to the amount of plastic material that is incinerated versus landfilled is well documented in many countries. In the U.S., the Environmental Protection Agency (EPA) estimates that 15% of plastic materials, regardless of type, will eventually be incinerated, with the rest being landfilled or recycled (see Appendix II for further detail). This percentage must be discounted from the calculations of emission reductions, to account for the volume of CO_2 that can be expected to be re-emitted. Where similar data exists in the country where the project is located, this data may be used to inform the discount factor. Appropriate data and data sources include host country officially

	published data, research studies or industry data. Any data or analysis used to inform the discount factor must be explained in the project documentation and assessed by the validation/verification body. The discount factor must distinguish between different types of plastics and/or be conservative for the type of plastic(s) that the project is producing. Where no similar data exists in the country where the project is located, a conservative global default factor may be used, as set out in Appendix II.

Data / Parameter	$FC_{,y}$
Data unit	TJ
Description	Energy content per unit of fuel type y
Equations	12
Source of data	IPCC
Justification of choice of data or description of measurement methods and procedures applied	The *IPCC Guidelines for National Greenhouse Gas Inventories* is internationally recognized and the data provided in the guidelines is peer reviewed.
Purpose of Data	Calculation of project emissions
Comments	N/A

Data / Parameter	$EF_{a,y}$
Data unit	tCO_2e/TJ
Description	Emission factor of fuel type y
Equations	12
Source of data	IPCC
Justification of choice of data or description of measurement methods and procedures applied	The *IPCC Guidelines for National Greenhouse Gas Inventories* is internationally recognized and the data provided in the guidelines is peer reviewed.
Purpose of Data	Calculation of project emissions
Comments	N/A

9.2 Data and Parameters Monitored

Data / Parameter	$Q_{gross,i,y}$
Data unit	metric tons of plastic type *i*
Description	Quantity of total plastic type *i* sold by the project into the market in time period y from eligible feedstocks
Equations	2 and 3
Source of data	Measurements at project facility
Description of measurement methods and procedures to be applied	Plastic material and additives must be weighed on scales that have available calibration procedures from the manufacturer.
Frequency of monitoring/recording	Daily or monthly
QA/QC procedures to be applied	Calibration of scales must be conducted according to the equipment manufacturer's specifications.
Purpose of data	Calculation of baseline emissions
Comments	N/A

Data / Parameter	$Q_{add,i,y}$
Data unit	metric tons of additive
Description	Quantity of any additives weighed before being put into the process.
Equations	2 and 3
Source of data	Measurements at project facility
Description of measurement methods and procedures to be applied	Additives must be weighed on scales that have available calibration procedures from the manufacturer. Additives may be added to the process to make the plastic more flexible or provide other desirable attributes. This supplemental material must be weighed prior to entering the process and subtracted out from the gross weight to obtain the net weight of plastic that has sequestered the GHGs.
Frequency of monitoring/recording	Daily or monthly
QA/QC procedures to be applied	Calibration of scales must be conducted according to the equipment manufacturer's specifications.
Purpose of data	Calculation of baseline emissions

Comments	N/A

Data / Parameter	$QF_{Per,y}$
Data unit	Percentage
Description	The percent of CH_4 during a specific production run of plastic which is qualifying (i.e., the percent of CH_4 that would have been vented to the atmosphere in the absence of the project).
Equations	7
Source of data	Project proponent, based on information from gas suppliers.
Description of measurement methods and procedures to be applied	Project proponent must obtain such information from the gas supplier about the source and baseline status (venting or destruction) of CH_4. The project proponent must interview each gas supplier for the project activity and present survey results to the validation/verification body (VVB), who may wish to interview gas supplier as well. The survey will include the following questions: • Is the gas supplier required by regulation to destroy the methane that is being provided to the project activity? Please describe and provide references to any applicable regulations. • Please provide historical data on any methane destroyed in previous years – including as a percentage of total methane output of the source.[7] Data should be provided from the last three years if available or for the operating history of the methane source if less than three years.
Frequency of monitoring/recording	Once per verification
QA/QC procedures to be applied	Project proponent must obtain information from the gas supplier about the source of methane. That documentation must be provided to the VVB for review.
Purpose of data	Calculation of baseline emissions. For qualifying methane, the GWP of methane is calculated in baseline emissions. For non-qualifying methane, the baseline emission is CO_2. But because that methane was captured instead of destroyed, the

[7] For example, if in the last three years, the methane source has destroyed an average of 25% of the estimated total output of the source, such data should be provided and $QF_{Per,y}$ would thus be 0.75.

	CO_2 associated with the combustion of CH_4 was not emitted and can therefore be counted as a baseline emission.
Comments	Where the captured and sequestered methane was sourced from a landfill that already has a landfill gas collection system, or where LFG is required to be captured and destroyed, that amount of methane must be assumed to be destroyed and emitted as CO_2. For example, where 60% of the methane for a project facility was sourced from a landfill with an LFG collection system and 40% from an anaerobic digestion facility on a farm that is not required to capture methane, $QF_{Per,y}$ equals 0.4.

Data / Parameter	$Q_{CO2,meter,y}$
Data unit	tCO_2
Description	Amount of CO_2 captured in year *y* to produce plastic material by the project, as determined by a flow meter
Equations	8
Source of data	Measurements at project facility
Description of measurement methods and procedures to be applied	Use calibrated flow meters. Calibration must be conducted according to the equipment manufacturer's specifications. The amount of CO_2 must be metered before entering the plastic production process and must be subject to standard calibration and QA/QC procedures for the measurement of critical data variables. This data must be crosschecked with a pre-production estimate of GHG-to-product ratios to ensure that GHG feedstock is not released during the production process. For example, a process may take two pounds of CO_2 to manufacture one pound of plastic. The project proponent must keep a record of all methane inputted into the process and provide an estimated percentage of qualifying and non-qualifying methane.
Frequency of monitoring/recording	Data must be monitored continuously and recorded on at least a daily basis.
QA/QC procedures to be applied	Calibration of meters must be conducted according to the equipment manufacturer's specifications.
Purpose of data	Calculation of baseline emissions
Comments	Project proponents may use a mass-flow meter to measure mass of CO_2. Project proponents may also use a volumetric meter to determine cubic feet or meters of gas collected, but this number

	must be converted to mass by multiplying the measured volume by the density of CO_2 or CH_4 at normal temperature and pressure (20 degrees C at 1 atmosphere). The density of CO_2 at NTP is 1.842 kg/m3.[8] The density of CH_4 at NTP is 0.668 kg/m3. Determining GHG input by direct measurement is intended to be used as a cross-check of the molecular formula ratio because a verifier cannot directly measure or test the exact molecular formula of the plastic resin. Because no process is 100% efficient, it would be expected that some GHGs that enter the process are lost at some point before the final plastic is produced. Thus, the measurements of GHGs via the meter should be greater than what is determined to be locked into the plastic through the molecular formula ratio for $Q_{p,i,y}$. Where the meter measurements are less, this situation should be explained or corrected to the satisfaction of the VVB

Data / Parameter	$Q_{CH4,meter,y}$
Data unit	tCH_4
Description	Amount of CH_4 captured in year *y* to produce plastic material by the project, as determined by a flow meter
Equations	8
Source of data	Measurements at project facility
Description of measurement methods and procedures to be applied	Use calibrated flow meters. Calibration must be conducted according to the equipment manufacturer's specifications. The amount of CH_4 must be metered before entering the plastic production process and must be subject to standard calibration and QA/QC procedures for the measurement of critical data variables. This data must be crosschecked with a pre-production estimate of GHG-to-product ratios to ensure that GHG feedstock is not released during the production process. For example, a process may take two pounds of CH_4 to manufacture one pound of plastic. The project proponent must keep a record of all methane inputted into the process and provide an estimated percentage of qualifying and non-qualifying methane.
Frequency of monitoring/recording	Data must be monitored continuously and recorded on at least a daily basis.
QA/QC procedures to be applied	Calibration of meters must be conducted according to the equipment manufacturer's specifications.

Purpose of data	Calculation of baseline emissions
Comments	Project proponents may use a mass-flow meter to measure mass of methane. Project proponents may also use a volumetric meter to determine cubic feet or meters of gas collected, but this number must be converted to mass by multiplying the measured volume by the density of CO_2 or CH_4 at normal temperature and pressure (20 degrees C at 1 atmosphere). The density of CH_4 at NTP is 0.668 kg/m3. Determining GHG input by direct measurement is intended to be used as a cross-check of the molecular formula ratio because a verifier cannot directly measure or test the exact molecular formula of the plastic resin. Because no process is 100% efficient, it would be expected that some GHGs that enter the process are lost at some point before the final plastic is produced. Thus, the measurements of GHGs via the meter should be greater than what is determined to be locked into the plastic through the molecular formula ratio for $Q_{p,i,y}$. Where the meter measurements are less, this situation should be explained or corrected to the satisfaction of the VVB

Data / Parameter	$Q_{elec,y}$
Data unit	MWh
Description	Quantity of electricity used by project facility supplied by the grid in year y
Equations	11
Source of data	Measurements at project facility or electric utility bills
Description of measurement methods and procedures to be applied	Use calibrated electricity meters. Calibration must be conducted according to the equipment manufacturer's specifications. Alternatively, utility billing data can be used.
Frequency of monitoring/recording	Data must be monitored continuously and recorded on at least a daily basis. If utility data is used, monthly bills are acceptable
QA/QC procedures to be applied	The consistency of metered electricity generation should be cross-checked with receipts from electricity purchases where applicable
Purpose of data	Calculation of project emissions
Comments	N/A

Data / Parameter	EF_{elec}
Data unit	tCO_2e/MWH
Description	Emission intensity of electricity

Equations	11
Source of data	US eGrid or utility data or similar source if the project is in another country.
Description of measurement methods and procedures to be applied	In developing countries, project proponents may use the "Tool to calculate the emission factor for an electricity system" to calculate this parameter. In the US, eGrid emissions factor for the sub-region where the facility is located (latest available information) may be used.
Frequency of monitoring/recording	Annual
QA/QC procedures to be applied	As per "Tool to calculate the emission factor for an electricity system"
Purpose of data	Calculation of project emissions
Comments	N/A

Data / Parameter	$Q_{ff,y}$
Data unit	Gallons (oil fuels), cubic meters (natural gas), metric tons (solid fuels)
Description	Quantity of fossil fuel used by the project facility in year y
Equations	12
Source of data	Measurements at project facility
Description of measurement methods and procedures to be applied	Use calibrated flow or gas meters. Calibration must be conducted according to the equipment manufacturer's specifications.
Frequency of monitoring/recording	Data must be monitored and recorded monthly.
QA/QC procedures to be applied	The consistency of metered fuel use should be cross-checked with receipts from fuel suppliers where applicable
Purpose of data	Calculation of project emissions
Comments	N/A

9.3 Description of the Monitoring Plan

The project must monitor all key variables, including the following:

- Quantity of CO_2 captured from the atmosphere as a GHG feedstock (where CO_2 is part of the GHG feedstock) for the plastic material. The capture process will capture CO_2, which will then be run through a meter to measure the amount of CO_2 captured in pounds or kg.

- Quantity of methane that is collected (if CH_4 is part of the GHG feedstock) must be piped or shipped into the production facility. The amount of methane captured must be measured through traditional metering methods.

  Note that both the CO_2 and CH_4 captured must be crossed checked with pre-defined, estimated ratios of GHG input to plastic output, which must be included in the quality control section of the monitoring tables. In addition, the project proponent is required to account for any GHGs that escape during the manufacturing process (although the point of measurement should be the latest point just prior to when the GHG feedstock combines with other materials to form the plastic material and is thus sequestered). To confirm the level of baseline emissions from the capture of the GHGs for sequestration into the plastic material, the project proponent must calculate both the MFR and the DMM (the stoichiometric ratio method and direct measurement method).

- Production of plastic material, as monitored through appropriate weighing techniques.
- In cases where methane is used as a feedstock, an analysis of whether that methane would be qualifying or non-qualifying.
- An analysis of the potential for leakage as described in Section 8.3 above.
- Quantities of electricity and any fossil fuel used at the facility (for project emissions). Gas and electricity meter readings shall be the primary method for monitoring these data parameters. Utility-supplied data (gas and electricity bills) are acceptable.

The project proponent must establish, maintain and apply a monitoring plan and GHG information system that includes criteria and procedures for obtaining, recording, compiling and analyzing data, parameters and other information important for quantifying and reporting GHG emissions relevant for the project and baseline scenarios. Monitoring procedures must address the following:

- Types of data and information to be reported;
- Units of measurement;
- Origin of the data;
- Monitoring methodologies (e.g., estimation, modeling, measurement and calculation);
- Type of equipment used;
- Monitoring times and frequencies;
- QA/QC procedures;
- Monitoring roles and responsibilities, including experience and training requirements;
- GHG information management systems, including the location, back up, and retention of stored data.

Where measurement and monitoring equipment is used, the project proponent must ensure the equipment is calibrated according to current good practice (e.g., relevant industry standards).

All data collected as part of monitoring must be archived electronically and kept at least for 2 years after the end of the last project crediting period. QA/QC procedures must include, but are not limited to:

- Data gathering, input and handling measures;
- Input data checked for typical errors, including inconsistent physical units, unit conversion errors;
- Typographical errors caused by data transcription from one document to another, and missing data for specific time periods or physical units;
- Input time series data checked for large unexpected variations (e.g., orders of magnitude) that could indicate input errors;
- All electronic files to use version control to ensure consistency;
- Physical protection of monitoring equipment;
- Physical protection of records of monitored data (e.g., hard copy and electronic records);
- Input data units checked and documented;
- All sources of data, assumptions and emission factors documented.

APPENDIX I: JUSTIFICATION OF THE ACTIVITY METHOD

Background

The concept of using greenhouse gases (GHGs) as a raw material for the production of useful products is only a few years old. A number of start-up companies are developing technologies that use captured GHGs to produce tangible products, with what has been termed “Carbon Capture and Utilization” (CCU). Products created through CCU processes can act as long-term storage of the captured GHGs used in their production and displace products created through conventional processes. The level of commercial activity for CCU products is very low, as it is a new technology. This is particularly true for the use of CCU to create plastic materials that could displace plastics produced through conventional processes in the commercial market.

As of the writing of this methodology, there is no large-scale commercial application of CCU technology to capture and sequester GHGs in plastic materials, and there is only limited activity in using CCU to produce concrete and other similar building materials. As of 2018, the company closest towards commercialization of CCU technology in the plastics sector has only a small plant that could provide materials for commercial customers, operated by a start-up company called Newlight Technologies, Inc. As a result, essentially 100 percent of all plastic materials in any market are produced using conventional, petroleum-based materials and processes, with the exception of some niche plastics made from food crops like corn or sugarcane, which do not sequester GHGs long-term.

In addition, it should be noted that as of the writing of this methodology, Newlight’s technology for CCU in plastic materials has been available for more than three years, demonstrating that while the project is commercially available at a modest scale, its growth has been limited – indicating barriers to penetration in the wider market.

Approach

The activity penetration option requires that the total amount of plastic production from this alternative, GHG-capturing process, does not amount to more than five percent of total plastic production worldwide. Activity penetration is equal to: Observed Activity (OA) divided by the Maximum Adoption Potential (MAP).

In this case, as mentioned above, this project activity has not reached commercial scale. The one company, Newlight Technologies, Inc., which produces the only known plastic material from GHG feedstock, has only a small pilot facility which has produced plastic for a few clients. However, this particular plastic used shipped CO_2 from another source, not a waste source like the flue gas from a power plant. Thus, the “total number of instances installed at a given date in year *y*” is zero, and OA can be considered to be zero.

Given the early stage of CCU technology, it is difficult to say exactly what the resource and other constraints are to adoption of this technology. The feedstocks, CO_2 and CH_4, are ubiquitous, and there are no particular barriers (e.g., market access or customer acceptance) that would limit the adoption of this technology. Thus, for the purposes of this methodology, the MAP is the entire market for each specific type of plastic the project facility will produce, within the country where that facility is located.

Therefore, clearly the activity penetration level of the project activity covered by this methodology is below the five percent threshold, and the project activity may be deemed additional.

Additionally, given the low penetration of this activity, the only baseline scenarios that are reasonable to consider are: 1) the continued manufacturing of traditional plastic material with no plastic production involving GHG sequestration or perhaps; 2) the large-scale adoption of this technology many years into the future, at which point the five percent threshold for activity penetration would be exceeded and the activity would no longer be eligible for crediting.

APPENDIX II: EMISSION FACTORS

Introduction

This appendix provides additional information about the calculation of the following emission factors:

1) EF_i: the emission factor for GHGs caused by the production of virgin plastic materials; and
2) DF_{EL}: the discount factor applied to account for the end of life of plastic material that is incinerated, releasing CO_2

Emission Factor for the Production of Plastic Material (EF_i)

Introduction and Background

This methodology relies on emission factors for each type of plastic produced by the project activity in order to calculate baseline emissions associated with the displacement of virgin plastic production (EF_i). This appendix provides additional information about how EF_i is determined, including default factors for projects located in the United States and the process that must be used by projects located outside of the United States to calculate EF_i.

Emissions associated with the manufacture of plastic materials through conventional processes include the extraction and processing of raw materials, which are primarily petroleum products, emissions associated with the manufacturing process itself, and emissions associated with the transportation of plastic materials. These emissions vary depending on the type of plastic material – the production of polypropylene, for example, generates almost 40% fewer emissions than the production of polystyrene.

Calculation of Default Factors for Projects in the United States

Projects located in the United States may use a default value for EF_i, based on the United States Environmental Protection Agency (U.S. EPA) Waste Reduction Model (WARM), which was created to calculate the GHG emissions of waste management practices in the United States, including from the recycling and landfilling of plastic materials.

The WARM model disaggregates the different sources of emissions associated with plastic production and includes process energy from the petroleum refining process, process non-energy emissions, and transportation emissions, as shown in Table 3a below[9]. For the purposes of this methodology, only process and process non-energy emissions are included because emissions from the transportation of plastic materials are not expected to be different in the baseline and project scenarios (e.g., because traditional plastic or GHG-containing plastic both must be transported to their final destination).

Note – The tCO_2e in Table 3a and Table 3b, below, are expressed in short tons. For the purposes of calculating baseline emissions in Equation 2, the default values included in Table 4, below, have been converted into metric tCO_2e.

[9] https://www.epa.gov/sites/production/files/2016-03/documents/warm_v14_containers_packaging_non-durable_goods_materials.pdf

Table 3a: Source Reduction Emission Factors for Plastic

Material (a)	Process Energy (b)	Transportation Energy (c)	Process Non-Energy (d)	Net emissions (e) [e=b+c+d]
HDPE	1.18	0.15	0.20	1.53
LDPE	1.40	0.15	0.21	1.76
PET	1.74	0.07	0.39	2.20
LLDPE	1.14	0.15	0.25	1.54
PP	1.17	0.13	0.21	1.51
PS	1.86	0.15	0.45	2.46
PVC	1.68	0.08	0.14	1.90

The WARM model takes into account that some plastic is created from recycled materials, and therefore not all plastic materials on the market are from 100% raw materials, in its calculation of net emissions from plastic production. Table 3b, below, includes the emissions from “raw material acquisition” for the current mix of recycled vs. virgin plastic in the market (column “b”), as opposed to column “c” which calculates the emission factor for 100% virgin inputs. Note that the values in Table 3b are negative because this section of the WARM model is referencing reductions in emissions for every ton of plastic where its use is avoided.

Note that the figures in column “e” in Table 3a do not match column “b” in Table 3b below. This is because the transportation energy in the WARM model does not include retail transportation, which is 0.04 tCO_2/t of plastic for all plastic types[10]. The values in column “e” of Table 3a are equal to: [net emissions from 100% virgin inputs, Table 3b] – [0.04].

10 See Table 5-4 on page 5-5: https://www.epa.gov/sites/production/files/2016-03/documents/warm_v14_containers_packaging_non-durable_goods_materials.pdf.

Table 3b: Raw Material Acquisition and Manufacturing Emission Factor for Virgin Production of Plastics (tCO_2e/Short Ton)

Material (a)	Raw Material Acquisition and Manufacturing for Current Mix of Inputs (b)	Raw Material Acquisition and Manufacturing for 100% Virgin Inputs (c)	Net Emissions for Current Mix of Inputs (d)	Net Emissions for 100% Virgin Inputs (e)
HDPE	-1.47	-1.57	-1.47	-1.57
LDPE	-1.80	-1.80	-1.80	-1.80
PET	-2.20	-2.24	-2.20	-2.24
LLDPE	-1.58	-1.58	-1.58	-1.58
PP	-1.55	-1.55	-1.55	-1.55
PS	-2.50	-2.50	-2.50	-2.50
PVC	-1.95	-1.95	-1.95	-1.95
Mixed Plastics	-1.92	-1.98	-1.92	-1.98

The net emission factor (EF_i) for each type of plastic is calculated as:

[(net emissions for current mix of inputs (Table 3b)) – (transportation energy (Table 3a)) – (retail transportation)] x (conversion factor from short tons to metric tons, equal to 1.102)

For example, the net emissions factor for HDPE would be equal to:

[(1.47) – (0.15) – (0.04)] x (1.102) = 1.41

There are a few types of plastic material eligible to be produced through project activities, but not included in the U.S. EPA WARM model report. These forms of plastic are:

- Thermoplastic urethane (TPU)
- Acrylonitrile butadiene styrene (ABS)
- Polycarbonate (PC)

Emission factors for these plastic materials were derived from a report prepared for the City of Winnipeg[11]. The emission factors included in this report are inclusive of emissions associated with transportation. Therefore, to calculate emission factors for ABS, TPU and PC that are equivalent to the emission factors for other eligible plastic materials, an estimate of transportation emissions was subtracted from the total emissions. The EPA data from the WARM model specifies 0.19 metric tons of CO_2/per short ton of plastic (equal to 0.21 metric ton of CO_2/per metric ton of plastic) as the highest (and therefore most conservative) value for emissions from transportation. This value was subtracted from total emissions for the emission factors for ABS, TPU and PC included in Table 4 below. It is reasonable to

11 https://www.winnipeg.ca/finance/findata/matmgt/documents/2012/682-2012/682-2012_Appendix_H-WSTP_South_End_Plant_Process_Selection_Report/Appendix%207.pdf

infer that transporting ABS, TPU and PC would be similar in cost and energy to all other types of plastics, a point reinforced by the fact that the transport figures in the WARM model (except for PVC) are all in a very small range. The emission factors for TPU and PC were derived from the "Other Plastics" emission factor.

Table 4: Default Emission Factors for EF_i for projects located in the United States

Plastic Type	Emission Factor (tCO_2e/metric ton of plastic material produced)
HDPE	1.41
LDPE	1.77
PET	2.30
LLDPE	1.53
PP	1.52
PS	2.55
PVC	2.02
ABS	3.25
TPU	2.49
PC	2.49

Note that project proponents must use the latest version of the WARM model (or similar sources of data in other countries) when developing a new project.

Discount Factor for Incinerated Plastic Material (DF_{EL})

Introduction

DF_{EL} is the discount factor that is applied to account for the fact that a certain amount of GHGs captured as part of the project may be re-released when plastic is incinerated. Where plastic materials that are made through project activities are incinerated, CO_2 would be released to the atmosphere through the combustion process, and therefore the incinerated plastic materials would not represent a permanent sequestration of the GHG feedstock used in the production process. DF_{EL} represents the proportion of incinerated plastic to non-incinerated plastic.

This section sets out in more detail the three ways that DF_{EL} can be determined: 1) a default value for U.S.-based projects; 2) criteria for projects to determine DF_{EL} where appropriate data is available, and; 3) a conservative global default value.

Default Factor for Projects Located in the United States

The U.S. Environmental Protection Agency (U.S. EPA) has collected and reported data on the generation and disposition of waste in the United States for more than 30 years. This information is used to measure the success of waste reduction and recycling programs across the country and characterize the U.S. national waste stream, and can be used to determine DF_{EL} in the United States.

Based on the information included in the U.S. EPA *Advancing Sustainable Materials Management: 2014 Fact Sheet Assessing Trends in Material Generate, Recycling, Composting, Combustion with Energy Recovery and Landfilling in the United States* (November 2016)[12], 15% of total plastics are incinerated in the U.S. Therefore, the default factor for DF_{EL} in the U.S. is: 0.15.

Procedure for Projects Located Outside of the United States

Where projects are located outside of the United States, they must determine the percent of plastic incinerated in the country or geographic region of the project in order to determine $DF_{EL.}$ Independent market estimates from government, academic or trade association sources may be used to determine the level of plastic incineration in a particular country. Where a single source does not include sufficient information to determine the percent of plastic incinerated in a particular country, multiple sources of data may be used. For example, where 5 million tons of waste is incinerated in a country and 10% of such waste is plastic products, then 500,000 tons of plastic may be assumed to be incinerated in that country. Where another source shows that 1.5 million tons of plastics is consumed in that country, then the default factor may be set at 30% (equal to: (plastic products incinerated) / (total plastic consumed) = (500,000) / (1,500,000)).

The project proponent must calculate DF_{EL} in terms of tCO_2e/metric ton of plastic material produced and apply this calculated discount factor to determine emissions in Equation 2.

Global Default Value

Where data is not available to determine a specific default factor for the percent of plastic that is incinerated in a particular country, a conservative global default value must be used. The conservative global default for DF_{EL} is: 0.40.

This conservative global default value for DF_{EL} is based on an estimate of the percent of plastic that is incinerated in Europe, which has the highest level of plastics incineration of any known country or region. According to a report from Plastics Europe[13], 36% of post-consumer plastic produced in Europe was incinerated for energy generation. Therefore, for the purposes of the methodology, where a project proponent cannot find data on the level of baseline plastics incineration in a country where a project facility is located, the global default value for DF_{EL} is conservatively set at 40%.

---

12 See *Table 1. Generation, Recycling, Composting, Combustion with Energy Recovery and Landfilling of Materials in MSW, 2014*,* in the column for “combustion as a percent of generation” in the *Advancing Sustainable Materials Management: 2014 Fact Sheet Assessing Trends in Material Generate, Recycling, Composting, Combustion with Energy Recovery and Landfilling in the United States* (U.S. EPA November 2016), which refers to the percent combusted as a percent of total waste generation for that category. and can be accessed at: https://www.epa.gov/sites/production/files/2016-11/documents/2014_smmfactsheet_508.pdf

13 http://vitalsigns.worldwatch.org/sites/default/files/vital_signs_trend_plastic_full_pdf.pdf, the original source is PlasticsEurope, *Plastics–The Facts 2014: An Analysis of European Plastics Production, Demand and Waste Data* (Brussels: 2014).

APPENDIX III: EXAMPLE CALCULATION FOR MOLECULAR FORMULA RATIO (MFR)

The molecular formula ratio (MFR) determines the quantity of CO_2 or CH_4 captured by observing the molecular formula of the final plastic material. As set out in Section 8 above, the project proponent must provide the molecular formula for each type of plastic *i*, and the formula for the conversion from the GHGs which convert to the plastic material. This appendix sets out an example of how to determine the MFR.

For example, where the plastic material has the molecular formula $C_4H_6O_2$, the project proponent will provide the following molecular formula:

$$33H_2 + 12O_2 + 4CO_2 \rightarrow C_4H_6O_2 + 30H_2O$$

The following calculations are used to derive the amount of CO_2 sequestered in a given quantity of the example plastic material above. The example calculation is based on the following conditions:

1) The plastic production process produces 27.7 metric tons of a plastic material;

2) The plastic has a molecular formula of $C_4H_6O_2$, with a molar weight of 86[14] grams per mole, equal to 55.8% carbon by weight; and

3) The carbon in the plastic material is 100% derived from sequestered CO_2, and CO_2 is 27.27%[15] carbon.

Therefore, to calculate the amount of CO_2 embodied in the final plastic material, the equation is as follows:

1) 27.7 MT of plastic material x 55.81% carbon in the material = 15.46 MT carbon in material.

2) If 100% of the carbon comes from CO_2, that means that of 15.46 MT carbon in the material, it would take 56.6 MT of CO_2 to provide enough carbon for the 15.46 MT. This is because the carbon in the CO2 is 27.27% of the weight of the CO_2 molecule[16]. If there are 56.6 MT of CO_2 required to produce 27.7 MT of plastic, the ratio of CO_2 embodied in the plastic material is 2.043:1 sequestered CO_2:plastic by weight.

3) Thus, the project proponent (and the validation/verification body (VVB)) would know that for every 100 metric tons of plastic produced, 204.33 metric tons of CO_2 is sequestered.

---

14 Molecular weight of carbon is 12, oxygen is 16 and hydrogen is 1. Therefore, $C_4H_6O_2$=12*4 + 1*6 + 16*2 = 86. The four carbon atoms amount to 48, and 48/86 = 55.8%.

15 The molecular weight of carbon is 12, oxygen is 16 and thus CO_2 = 44. The percentage of weight that is carbon is 12/44 or 27.27%.

16 15.46 MT / 0.2727 = 56.6 MT

Example of quantifying GHGs sequestered when CO_2 is used as a feedstock:

As Equation 5 states:

$$Q_{CO2.seq,y} = \sum_i \{[Q_{p,i,y} * (MW_C / MW_{p,i})] / RCM_{CO2}\}$$

Where:

$Q_{CO2,seq,y}$	= amount of CO_2 captured in year *y* to produce plastic material *i* by the project (metric tons per year)
$Q_{p,i,y}$	= Net quantity of plastic type *i* produced by the project in year *y* (metric ton)
MW_C	= the molecular weight of the carbon in the plastic material *i* (g/mol)
$MW_{p,i}$	= the total molecular weight of the plastic material *i* (g/mol)
RCM_{CO2}	= the fraction of carbon as part of the carbon dioxide molecule (% carbon in carbon dioxide by molar weight or 27.27%)

If $Q_{p,i,y}$ were 27.7 tons, using the numbers from the above example would yield the following:

$$Q_{CO2.seq,y} = [Q_{p,i,y} * (MW_C / MW_{p,i})] / RCM_{CO2}$$

$Q_{CO2.seq,y}$ = [27.7 * (48/86)] / 0.2727 = 56.6 metric tons of CO_2 sequestered

METHODOLOGY FOR THE REDUCTION OF ENTERIC METHANE EMISSIONS FROM RUMINANTS THROUGH THE USE OF 100% NATURAL FEED SUPPLEMENT

Version 1.0

22 November 2019

Sectoral Scope 15

This methodology was developed by

MOOTRAL

Document Prepared by MOOTRAL SA

Author: Elsa Zoupanidou (Mootral SA)

Mootral would like to acknowledge the many contributions by colleagues at Mootral SA: Maria Sünkel, Deepashree Kand, Hilde Vrancken, Matthias Miller, and Oliver Riede. Appreciation is extended to Isabelle Botticelli (Mootral SA) and Michael Mathres (Mootral SA) who provided useful suggestions and support over the entire period of the development of the Methodology. We are grateful to Silvana Claassen (Climate Neutral Group), Sergi Cuadrat (Allcot AG), and Mercedes Garcia Madero (Allcot AG) for their contribution and suggestions for improvements. Finally, we thank our reviewers, whose comments and suggestions contributed to greatly increase the clarity and effectiveness of this manuscript.

TABLE OF CONTENTS

1 SOURCES

This methodology was developed based on the requirements and guidelines of the following:

- *VCS Standard, v4.0*
- *VCS Methodology Requirements, v4.0*
- *VCS Guidance: Guidance for Standardized Methods, v3.3*
- *2006 IPCC Guidelines for National GHG Inventories. Volume 4: Agriculture, Forestry and Other Land Use. Chapter 10: Emissions from livestock and manure management*

The following have informed the development of this methodology:

- *VCS module VMD0027: Estimation of domesticated animal populations, v1.0*
- *VCS module VMD0028: Estimation of emissions from domesticated animals, v1.0*
- *"Quantification Protocol" approved by the Alberta Offset System: Quantification protocol for reducing greenhouse gas emissions from fed cattle (version 3.0)*
- *ACR Methodology for Grazing Land and Livestock Management, v1.0*

2 SUMMARY DESCRIPTION OF THE METHODOLOGY

This methodology provides procedures to estimate enteric methane (CH_4) emission reductions generated from the inhibition of methanogenesis due to the introduction of a natural feed supplement into ruminants' diets. This methodology considers only emission reductions from enteric fermentation.

Feed supplements applicable under this methodology reduce CH_4 emissions by directly acting on the population of methanogenic archaea in the rumen. This methodology focuses on application of natural plant-based feed supplements, which along with inhibiting methanogenesis, may also have advantageous effects on rumen bacteria, thereby improving fermentation in the rumen.

Depending on the location where a project is implemented and data availability, this methodology provides three approaches for the quantification of baseline emissions and two approaches for the quantification of project emissions. Specifically, the quantification of baseline emissions may be performed using data from either on-site direct measurements, or by applying one of two different Intergovernmental Panel on Climate Change (IPCC)-approved methods to model emissions using country-specific or peer-reviewed biometric data. The quantification of project emissions may be performed using data from either on-site direct measurements, or by applying an empirically-derived regional emission reduction factor provided by the feed supplement manufacturer.

Table 2: Additionality and Crediting Baseline Methods

Additionality and Crediting Method	
Additionality	Activity method
Crediting Baseline	Project Method

3 DEFINITIONS

In addition to the definitions set out in VCS document *Program Definitions*, the following definitions apply to this methodology:

Animal Group
Animals at each farm grouped based on a homogenous ruminant population characterization such as animal type, weight, production phase (e.g., pregnant or lactating cow) and feed type

Diet
Feed ingredients or mixture of ingredients including water, which is consumed by animals

Dry Matter Intake (DMI)
All nutrients contained in the dry portion of the feed consumed by animals

Emission Reduction Factor
Percent reduction of enteric methane emissions per animal due to project feed supplement

Enteric Methane
Methane emissions from ruminants, due to enteric fermentation, as part of the digestion of feed materials

Enteric Fermentation
A natural part of the digestive process of ruminants where microbes decompose and ferment food present in the digestive tract or rumen. Enteric methane is one by-product of this process and is expelled by the animal through burping.

Feed(s)
Edible material(s) which are consumed by animals and contribute energy and/or nutrients to the animal's diet

Feed Supplement
A feed added to an animal's regular diet to improve the nutritive balance of the total mixed ration (or any other purpose, such as reduction of methane emissions) and intended to be (i)

fed undiluted as a supplement to other feeds; (ii) offered free-choice with other parts of the feed; or (iii) further diluted and mixed to produce a complete feed

Gross Energy
The total caloric energy contained in feed

Livestock Production Operation
An agricultural setting, permanent or semi-permanent facility or non-grazing area, where domesticated animals are kept or raised either indoors or outdoors to provide traction or for livestock commodities purposes1

Methanogenesis
The formation of methane in the rumen by microbes known as methanogens

Neutral Detergent Fiber (NDF)
A measure of total structural components (i.e., lignin, hemicellulose, cellulose, tannins and cutins) within the cells of plants that provides an estimate of fiber constituents of feedstuffs and indicates maturity; the higher the value, the more mature and lower quality the forage

Rumen
The large first compartment of the stomach of a ruminant where fermentation occurs, which allows for the digestion of fiber and other feeds

Ruminant
A mammal that has a different digestive system to monogastric (single stomach) animals. The primary difference is that ruminants' "stomach" consists of four compartments. The ruminants are able to acquire nutrients from plant-based food by fermenting it in the biggest compartment, the rumen, prior to digestion. Ruminating mammals include species like cattle, goat, sheep, deer, giraffes and antelopes.

4 APPLICABILITY CONDITIONS

This methodology applies to project activities which reduce enteric methane (CH_4) emissions through the inhibition of methanogenesis due to the introduction of a natural feed supplement into ruminants' diets.

The methodology is applicable under the following conditions:

1. Livestock producers must feed their animals a natural feed supplement which reduces enteric CH_4 emissions by direct inhibition of methanogens in the rumen.

1 FAO. Shaping the Future of Livestock. Berlin, 18–20 January 2018 http://www.fao.org/3/i8384en/I8384EN.pdf

2. Only ruminant animals shall be included in the project.

3. The project feed supplement must meet the following conditions:

    a. The active ingredients of the feed supplement must be 100% natural plant-based or macroalgae-based and non-GMO. This includes extracted components of plants. The feed manufacturer must provide a non-GMO certificate based on lab analysis.

    b. The feed supplement must have been demonstrated to comply with all feed and food regulations in each national or subnational (including local) jurisdiction in which it is consumed. Where conflict arises between regulations, the most stringent standard must apply.

    c. The feed supplement must have no significant negative health or performance impacts on the animal to which it is fed. Where conflict arises between regulations, the most stringent standard must apply.

    d. The feed supplement must be used as per feeding instructions provided by the manufacturer. The instructions provide critical defining conditions to secure the default level of reduction of the enteric methane emissions, such as the feeding routine and dose of supplement per kg of DMI to the animal.

4. Emission reductions generated by the use of other feed supplements and/or activities (e.g., improving animal productivity or nutritional and management strategies), the objective of which does not lead to the inhibition of methanogenesis, cannot be claimed through this methodology. This is to prevent overestimation of emission reductions achieved.

5. The implementation of project activities must confirm that the herd of ruminants in a given operation is fed the project feed supplement. For this purpose, the project proponent must be able to trace the feed supplement fed to livestock from the producer to on-farm consumption.

6. Evidence must be provided that there will be no increase in the manure emissions due to feed supplementation (e.g., evidence-based literature, peer-reviewed publications, study reports).

7. Baseline emissions included in this methodology are CH_4 production from enteric fermentation and are determined as the average activity over at least three continuous years prior to project implementation. Therefore, the project activities are required to meet the following conditions:

    a. Where project areas involve livestock farms that were operating prior to the start of project activities, reliable data (e.g., gross energy intake and dry matter intake) per animal group must be available for a minimum of two years where using baseline emissions Option 1 and three years where using baseline emissions Option 2. See Section 8.1 below for further details on options for quantifying baseline emissions.

    b. Where project areas involve livestock farms for which no farm records or farming data are available, the project proponent must be able to provide evidence to substantiate the animal group to which each new project area is allocated according to the average group as described in national or regional statistical accounts (i.e., the baseline emissions will be considered as the average activity of where the project is located).

5 PROJECT BOUNDARY

The spatial extent of the project boundary encompasses all geographic locations of supplement production, supplement transport, and project activity locations where natural feed supplement is part of the livestock production operation.

Table 3 below indicates the emission sources and GHGs included in the project boundary and the GHGs to be monitored.

Table 3: GHG Sources Included In or Excluded From the Project Boundary

Source		Gas	Included?	Justification/Explanation
Baseline	Enteric Fermentation	CO_2	No	No changes in biogenic CO_2 emissions are expected due to the project activity.
		CH_4	Yes	CH_4 emissions from enteric fermentation, prior to the project technology implementation, represent the major source of emissions in the baseline scenario.
		N_2O	No	No changes in biogenic N_2O emissions are expected due to the project activity.
Project	Enteric Fermentation	CO_2	No	No changes in biogenic CO_2 emissions are expected due to the project activity.
		CH_4	Yes	CH_4 emissions from enteric fermentation are the major source of emissions in the project scenario.
		N_2O	No	No changes in biogenic N_2O emissions are expected due to the project activity.
	Supplement Production and Transport	CO_2	Yes	CO_2 emitted from supplement transportation and production.
		CH_4	Yes	CH_4 may be emitted from combustion of fossil fuels during the processing.
		N_2O	No	N_2O emissions are not expected during the production process.

As indicated in the table above, the project boundary includes CH_4 emissions from enteric fermentation. The dominant pathway for CH_4 emissions from enteric fermentation is exhalation, and therefore CH_4 emissions need only be monitored via exhalation. The project boundary does not include CH_4 emissions from flatulence, because changes in methanogenesis will not impact the fixed ratio of methane released between exhalation and flatulence due to physiology of the rumen (i.e., a decrease in exhaled methane corresponds to a decrease in methane flatulence). Further, due to rumen physiology, changes in methanogenesis does not impact manure decomposition. For this reason, the project boundary also does not include CH_4 or N_2O emissions from decomposing manure.

Ruminants release methane by exhaling the gas mainly through their mouth and nostrils. Enteric CH_4 is produced mainly in the rumen (90%) and, to a smaller extent (10%), in the large intestine (Muray et al., 1999; Dini et al., 2012). Feed supplements that inhibit rumen methanogenesis cannot influence the ratio of enteric methane emissions in exhaled air compared to methane emissions in extracted feces due to the ruminants' physiology. The specific and direct inhibition of the methanogenesis in the rumen is not demonstrated to cause a major change in the overall rumen fermentation as this process is downstream of these metabolic processes.

Consequently, feed supplements will not impact digestion in a way that would lead to an increase in the CH_4 or N_2O emissions in the manure decomposition. Keuzer et al. (2006) concluded, in fact, that feed additives designed to limit methane emissions reduced methane emissions from both the digestive track and manure decomposition. Another study by Nampoothiri et al. (2015) reports that, in general, dietary manipulations have very little effect on manure N_2O production. Further studies (Aguerre et al, 2011; Aguerre et al, 2012; Hristov et al, 2012) verified that methane reduction achieved by manipulating the rumen fermentation had no change in manure emissions. The emissions from this element are expected to be equal or lower in the project as compared to the baseline scenario. Avoidance of increase in the manure emissions due to feed supplementation is dealt with by the applicability condition 6 of this methodology.

6 BASELINE SCENARIO

At the project start date, the most plausible baseline scenario must be identified as the continuation of livestock operations following business as usual practices (i.e., typical feeding regime without using a natural feed supplement to reduce CH_4 enteric fermentation). There are no plausible alternatives to this baseline scenario.

7 ADDITIONALITY

This methodology uses an activity method for the demonstration of additionality. Project proponents applying this methodology must determine additionality using the procedure below:

Step 1: Regulatory surplus

The project proponent must demonstrate regulatory surplus in accordance with the rules and requirements regarding regulatory surplus set out in the latest version of the *VCS Standard*.

Step 2: Positive list

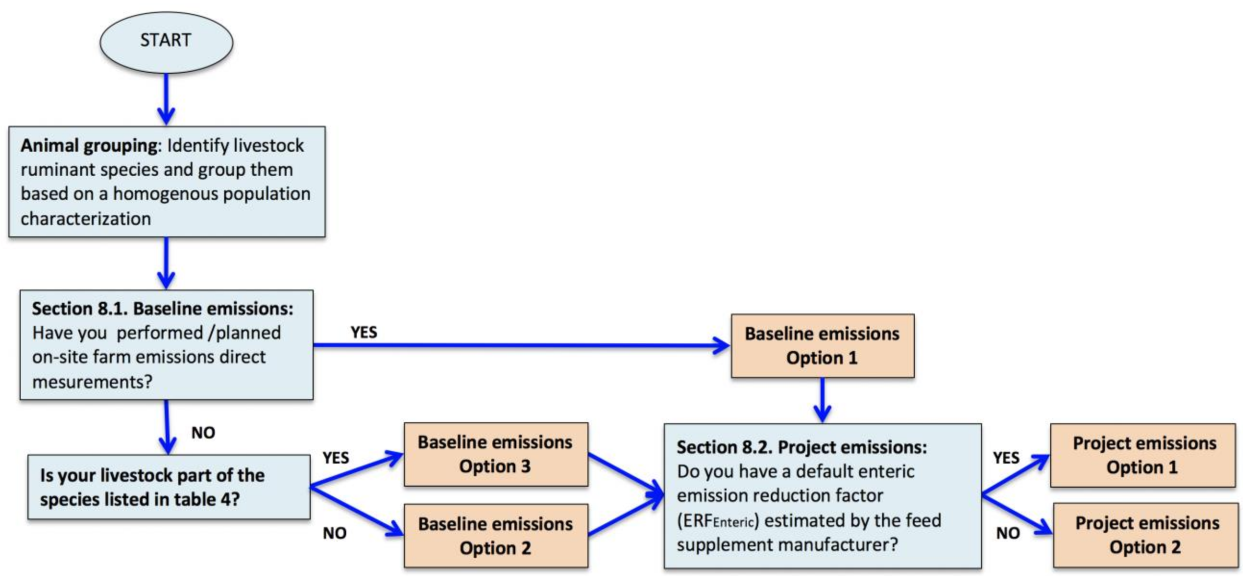
The applicability conditions of this methodology represent the positive list. The project must demonstrate that it meets all of the applicability conditions, and in so doing, it is deemed as complying with the positive list. The positive list was established using the activity penetration option (Option A in the *VCS Methodology Requirements*).

Justification for the activity method is provided in Appendix I.

8 QUANTIFICATION OF GHG EMISSION REDUCTIONS AND REMOVALS

This methodology proposes three approaches for the quantification of baseline emissions and two approaches for the quantification of project emissions, the applicability of each being dependent on data availability. Figure 1 outlines the steps involved in determining baseline and project emissions. The steps are listed below and explained in more detail in the following sections.

Figure 1: Decision Tree for CH_4 Emissions from Enteric Fermentation



8.1 Baseline Emissions

Emissions in the baseline scenario are estimated as the sum of annual emissions from enteric fermentation according to the following equation:

$$BE_{Enteric_{\mathbf{i}}} = \sum_{j=1}^{N} [EF_{Enteric_{i,j}}] \bullet \frac{GWP}{1000} \quad (1)$$

Where:

$BE_{Enteric_i}$ Total baseline CH_4 emissions from livestock enteric fermentation for farm *i* (tCO_2e).

Where the project activity includes multiple farms, emissions in the baseline scenario are estimated as the sum of annual emissions from each farm *i*: $\sum_{i=1}^{N}[BE_{Enteric_{\mathbf{i}}}]$

$EF_{Enteric_{i,j}}$ Enteric CH_4 emissions factor for each animal group *j* during the monitoring period (kg CH_4 $group^{-1}$)

GWP Global Warming Potential of methane (tCO_2/tCH_4)

1000 kg per one metric tonne

i Identification of livestock farm (1,2,..,N)

j Animal grouping (1,2,..,N).

This methodology provides three options for determining the enteric emissions factor ($EF_{Enteric_j}$). Depending on the availability of relevant project data and measurements, each project proponent must choose the most appropriate of the following options for each animal grouping.

$EF_{Enteric_{ij}}$ Option 1

Option 1 calculates the enteric emission factor for each animal group by performing direct enteric methane measurements to estimate the methane production per animal group per day (enteric emissions production factor - $EF_{Production_{i,j}}$). The enteric emissions production factor for each animal group measured by the chosen technology must be available at the validation. Therefore, using Option 1, the enteric emission factor for each animal group is calculated as follows:

$$EF_{Enteric_{\mathbf{i,j}}} = EF_{Production_{i,j}} \bullet N_{i,j} \bullet Days_{i,j} \quad (2)$$

Where:

$EF_{Enteric_{i,j}}$ Enteric CH4 emissions factor for each animal group j during the monitoring period (kg CH4 $group^{-1}$)

$EF_{Production_{i,j}}$ Average enteric emissions production factor for each animal group during the baseline or monitoring period (on-site direct measurement by chosen technology2) (kg CH4 head-1 day-1)

2 See Appendix II

$Days_{i,j}$	Number of days for each animal in the group j during the monitoring period in farm *i*
$N_{i,j}$	Average number of head in each animal grouping *j* in the farm *i* in the monitoring period (head)
i	Identification of livestock farm (1,2,..,N)
j	Animal grouping (1,2,..,N)

Baseline emission production factor ($EF_{Production}$) may be measured prior to project implementation with a sample for each animal group subsequently included in the project. Alternatively, a control group for each animal group can be used during project implementation, thus allowing baseline monitoring and project monitoring to occur simultaneously. The control group is used as a baseline measure and is identical to all other animals with the exception that it does not receive the feed supplement. $EF_{Production}$ remains fixed for the project crediting period once determined. Please see Appendix II for further details regarding the direct methane measurement technologies and procedures.

Two years of farm-specific data (e.g., gross energy intake and dry matter intake) prior to project implementation must be provided during validation. This data will be used to demonstrate that the Option 1 measured baseline does not represent a biased event as compared to the prior conditions at the farm, and therefore the $EF_{Production}$ reflects the average activity of where the project is located.

$EF_{Enteric_{ij}}$ Option 2

Option 2 provides procedures to calculate the enteric emission factor for each animal group by applying an IPCC Tier 2 method, using the following equation. The emission factor for each animal group is calculated as follows:

$$EF_{Enteric_{\mathbf{i,j}}} = \left[GE_{\mathbf{j}} \bullet Y_{\mathbf{m},\mathbf{j}} \bullet N_{i,j} \bullet Days_{i,j}\right] \bullet EC^{-1} \quad (3)$$

Where:

$EF_{Enteric_{i,j}}$	Enteric CH4 emissions factor for each animal group j during the monitoring period (kg CH4 $group^{-1}$)
GE_j	Average gross energy intake per animal grouping *j* in the farm *i* (MJ $head^{-1}$ day^{-1})
Ym_j	Conversion factor (Ym) indicates the proportion of the animal grouping j gross energy intake (GE) converted to enteric CH_4 energy. Energy of CH_4 as a percentage of GE (dimensionless).

Days	Number of days for each animal in the group j during the monitoring period in farm *i*[3]
$N_{i,j}$	Average number of head in each animal grouping *j* in the farm *i* in the monitoring period (dimensionless)
EC	Energy content of methane (=55.65 MJ kg^{-1} of CH_4)
i	Identification of livestock farm (1,2,..,N)
j	Animal grouping (1,2,..,N)

Gross energy intake *GE* is calculated by multiplying dry matter intake by the energy density of the feedstuff, using Equation 4:

$$GE_j = [DMI_j \bullet ED] \tag{4}$$

Where

DMI $_j$ — Average dry mass of feed consumed by animal group j in a given day (Kg $head^{-1}$ day^{-1})

ED — Energy Density. Average energy content of dry matter [MJ kg^{-1}] =

- 18.45 MJ kg^{-1} may be used as a default for diets including edible oils with fat contents in the range of 4 to 6%.
- 19.10 MJ kg^{-1} may be used as a default for diets including edible oils with fat contents below 4%.

$EF_{Entericij}$ Option 3

Option 3 is only suitable for animal species listed in Table 4 below, and where the project proponent does not have the required data for Option 2. The enteric emission factor for each animal group, is calculated as follows:

$$EF_{Enteric_{i,j}} = [EF_{i,j} \bullet N_{i,j} \bullet Days_{i,j} \bullet DF_j] \tag{5}$$

Where:

$EF_{Enteric_{i,j}}$ — Enteric CH_4 emissions factor for each animal group *j* during the monitoring period (kg CH_4 $group^{-1}$)

3 Note that the number of days could be less than 365. For example, in the case of young cattle the number of days represents the length of stay in a specific group.

$EF_{i,j}$	Average enteric CH_4 emissions factor for each animal group *j* during the monitoring period (country or regional specific factors, or those provided in Table 4), (kg CH_4 $head^{-1}$ day^{-1})
Days	Number of days for each animal in the group *j* during the monitoring period in farm *i*
$N_{i,j}$	Average number of head in each animal grouping in the farm *i* in the monitoring period; dimensionless
i	Identification of livestock farm (1,2,..,N)
j	Animal grouping (1,2,..,N)

Table 4: Enteric Fermentation Emission Factors for Tier 1 Method 1 (kg CH_4 $head^{-1}$ day^{-1})

Livestock	Emission Factor
Buffalo	0.15
Sheep	0.02[4]
Goats	0.01
Camels	0.13
Deer	0.05
Alpacas	0.02
Other (e.g., Llamas)	To be determined[5]
Note: All estimates are ±30-50% Sources: 2006 IPCC Guidelines for National Greenhouse Gas Inventories, Volume 4, Chapter 10, table 10.10. and background paper by Ulyatt, J. et al.	

8.2 Project Emissions

4 For developing countries the emission factor is 5 kg CH4 $head^{-1}$ yr^{-1}. IPCC is an intergovernmental body of the United Nations therefore we assume countries are classified accordingly.

5 One approach for developing the approximate emission factors is to use the Tier 1 emissions factor for an animal with a similar digestive system and to scale the emissions factor using the ratio of the weights of the animals raised to the 0.75 power. Liveweight values have been included for this purpose. Emission factors should be derived on the basis of characteristics of the livestock and feed of interest and should not be restricted solely to within regional characteristics.

Emissions in the project scenario are estimated as the sum of annual emissions from enteric fermentation, and from the production and transport of the supplement, according to the following equation:

$$PE_{Enteric\ i} = \sum_{j=1}^{N}[\mathrm{EF}_{\mathrm{Enteric}_{ij}}] \bullet [1 - \mathrm{ERF}_{\mathrm{Enteric}_j}] \bullet \frac{GWP}{1000} + \mathrm{EFME}_i \quad (6)$$

Where:

$PE_{Enteric_i}$	Total project enteric CH_4 emissions from livestock enteric fermentation for farm *i,* and the production and transport of the supplement used during the monitoring period (tCO_2e) Where the project activity includes multiple farms, emissions in the project scenario are estimated as the sum of annual emissions from each farm *i*: $\sum_{i=1}^{N}[\mathrm{PE}_{\mathrm{Enteric}_i}]$
$EF_{Enteric_{i,j}}$	Enteric CH_4 emissions factor for each animal group during the monitoring period as determined in Equation 2, 3 or 5 above (kg CH_4 $group^{-1}$)
$ERF_{Enteric_j}$	Enteric CH_4 emissions reduction factor (default or determined percentage value). Supplement's percentage reduction of the enteric CH_4 per animal in an animal group *j* during the monitoring period.
$EFME_i$	Total emissions associated with manufacturing and transport of the feed supplement in the farm *i* during the monitoring period (tCO_2e)
GWP	Global Warming Potential of methane (tCO_2/tCH_4)
1000	kg per one metric tonne
i	Identification of livestock farm (1,2,..,N)
j	Animal grouping (1,2,..,N)

8.2.1 Enteric methane emissions reduction factor

There are two options to calculate the enteric methane emission reduction factor:

$ERF_{Enteric}$ Option 1: Apply the default enteric emission reduction factor (%) estimated by the manufacturer of the feed supplement and calculate the emissions using Equation 6.[6] This option may only be used where the enteric methane emission reduction factor provided by the manufacturer of the feed supplement is supported by peer-reviewed literature or farm-specific emissions data that was determined by following the guidelines specified in Appendix II. This

6 The default factor provided by the manufacturer must meet the requirements for default factors set out in Section 2.5.2 of the *VCS Methodology Requirements v4.0*.

information must be provided for review at validation and at each verification. Additionally, there must be no significant differences between project parameters (e.g., feed regime, animal type, weight, production phase, geographic region, and management practices) and the manufacturer's default enteric emission reduction factor study design. Where there are significant differences between the project parameters and the manufacturer's study design, the project must use Option 2.

$ERF_{Enteric}$ Option 2: Determine the enteric methane emissions reduction factor for each animal group by performing direct enteric methane measurements to estimate the methane production per animal group per day while consuming the feed supplement during the monitoring period. The feed supplement's enteric emission reduction factor will be quantified by comparing actual project performance to enteric emission factors determined when quantifying baseline emissions, using Equation 7.

Enteric emissions reduction factor calculation:

$$\text{ERFEnteric}_{i,j} = \frac{EF_{Enteric\ \boldsymbol{i,j}} - (\,PE_{\ \boldsymbol{j}} \bullet N_j * Days)}{EF_{Enteric\ \boldsymbol{i,j}}} \bullet 100 \qquad (7)$$

Where:

$ERF_{Enteric_{i,j}}$	Enteric CH_4 emissions reduction factor for each animal group *j* in farm *i* (default percentage value)
$EF_{Enteric_{i,j}}$	Enteric CH_4 emissions factor for each animal group *j*, determined using Option 1, 2 or 3 in Section 8.1 above (kg CH_4 $group^{-1}$)
$PE_{i,j}$	Average enteric emissions production factor for each animal group *j* during the monitoring period in farm *i* (on-site direct measurement by chosen technology[7]) (kg CH_4 $head^{-1}$ day^{-1})
$N_{i,j}$	Average number of head in each animal grouping *j* in the farm *i* in the monitoring period; dimensionless
$Days_{i,j}$	Number of days for each animal in the group *j* during the monitoring period in farm *i*
i	Identification of cattle farm (1,2,..,N)
j	Animal grouping (1,2,..,N)

7 See Appendix II, Table 7: Measurement technologies of enteric methane emissions

8.2.2 GHG emissions from feed supplement manufacturing and transport

Emissions from the feed supplement are estimated by including all GHG sources from manufacturing and transport. Accounting for these GHG sources is not required for a project where such emissions are shown to be *de minimis*[8]. Otherwise, these emissions must be estimated as follows:

$$EFME_i = \frac{FM_i \bullet EF_P}{1000} + EF_{T\,i} \qquad (8)$$

Where:

$EFME_i$	Total emissions associated with manufacturing and transport of the feed supplement in the farm *i* during the monitoring period (tCO_2e)
FM_i	Amount of feed supplement purchased by the farm *i* during the monitoring period (kg)
EFP	Emission factor for production of feed supplement (kg CO_2e kg^{-1})
EFT	Emissions for transport of feed supplement consumed during monitoring period to the farm *i* (tCO_2e)

Project emissions from the production of the feed supplement at the manufacturer's production facility are calculated as:

$$EF_P = (Q_{elec} \bullet EF_{elec}) + (Q_{ff\,a} \bullet FC_a \bullet EF_a) \qquad (9)$$

Where:

Q_{elec}	Quantity of electricity from the grid used per kilogram of feed supplement production MWh kg^{-1}) during the monitoring period. To be determined by the feed supplement manufacturer.
EF_{elec}	Emissions factor for electricity (kg CO_2 MWh^{-1})[9]
Qff_a	Quantity of fossil fuel type *a* used per kilogram of feed supplement production during the monitoring period (volume or kg fuel/kg feed supplement). To be determined by the feed supplement manufacturer.

8 The pool or source may be excluded only if it is determined to be insignificant using appropriate approved tools for significance testing (e.g., the CDM "Tool for Testing Significance of GHG Emissions in A/R CDM Project Activities", available at http://cdm.unfccc.int/EB/031/eb31_repan16.pdf).

9 The latest approved version of CDM tool "Tool to calculate the emission factor for an electricity system" may be used to determine EF_{elec} if country or state/province values are not available.

FC_a Energy content per unit of fuel type *a* combusted (terajoule or TJ/ volume or kg fuel).

EFfuel Emission factor of fuel type *a* (kg CO_2e/ TJ).

a Fossil fuel type

Project emissions from the transport of the feed supplement to the project site are calculated as:

$$EF_T = TEF_i \bullet D_i \bullet FM_i \quad (10)$$

Where:

TEF_i Tonnes per km or miles of CO_2 emitted by transport mode *m* per kg of feed delivering feed supplement consumed during the monitoring period to farm *i* (t CO_2 $kg^{-1}km^{-1}$)

D_i Distance travelled by transport mode *m* delivering feed supplement consumed during the monitoring period to farm *i* (km or miles)

FM_i Amount of feed supplement purchased by the farm *i* during the monitoring period (kg)

8.3 Leakage

In the context of this methodology, leakage could potentially consist of a change in the number of animals in the livestock operation due to livestock performance impacts of introducing the supplement, thereby necessitating changes in livestock populations in non-project operations to fulfill market demand. However, supplements are expected to have an insignificant impact on livestock performance. Additionally, due to the economics of livestock production, it is unlikely that the costs and risks associated with increasing or decreasing the number of animals in the operation is justified from the minimal expected changes in animal performance alone. Therefore, leakage is considered to be zero.

8.4 Net GHG Emission Reductions and Removals

Net GHG emission reductions are calculated as follows:

$$ER_{Enteric\ i} = \sum_{i=1}^{N}[BE_{Enteric\ i} - PE_{Enteric\ i}] \quad (11)$$

Where:

$BE_{Enteric_i}$ Total GHG emission reductions due to project activities during the monitoring period (tCO2e)

$BE_{Enteric_i}$	Total baseline enteric CH_4 emissions from livestock enteric fermentation in the farm *i* during the monitoring period (tCO_2e)
$PE_{Enteric_i}$	Total project enteric CH_4 emissions from livestock enteric fermentation in the farm *i,* and the production and transport of the supplement used during the monitoring period (tCO_2e)
i	Identification of farm (1,2,..,N)

9 MONITORING

9.1 Data and Parameters Available at Validation

Data / Parameter	GE_j
Data unit	MJ head^{-1} day^{-1} of dry matter
Description	Average gross energy intake for a specific animal group
Equations	3
Source of data	Records and data from livestock operator or associated partners for three continuous years of historical data prior to the initiation of the project or from national/regional statistical accounts. Records and data during the project implementation also required.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	Gross energy intake can be calculated by dividing dry matter intake by the energy density of the feedstuff using equation 4 The gross energy (GE) content of the diets is calculated based on the fat level of the diets, therefore the livestock operator or associated partners need to demonstrate the fat content of the diet. Parameter to be updated with any change in the animal's feeding regime.
Purpose of Data	Calculation of baseline emissions
Comments	Calculated based on measured Daily Dry Matter Intake (DMI)

Data / Parameter	DMI_j
Data unit	Kg head^{-1} day^{-1}
Description	Average dry mass of feed consumed by an animal in a given day
Equations	4

Source of data	Records and data from livestock operator or associated partners for three continuous years of historical data prior to the initiation of the project or from national/regional statistical accounts. Records and data during the project implementation also required.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	Data must be provided by the livestock operator or associated partners for each animal group. The farm records must document the average daily dry matter intake by animal grouping in the project. Parameter to be updated with any changes in the animal's feeding regime.
Purpose of Data	Calculation of baseline emissions
Comments	Required to calculate gross energy intake for equation 3

Data / Parameter	Ym_j
Data unit	Dimensionless
Description	Percentage of feed energy converted to methane for each animal group
Equations	3
Source of data	Country or regional and population specific Ym values should be used when available to better reflect the ruminants' population characteristics. Default values provided in Table 7 or 8 (Appendix III) may be used as an alternative where regional values are not available.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	National environmental agencies or similar government and research institutions have accurate peer-reviewed studies that provide Ym values. Therefore, these values must be preferred and used where direct applicability can be demonstrated. The IPCC default values for the Ym (Table 7 in Appendix III) are provided for the different animal categories which can be used when no respective values are available from country-specific research. The associated uncertainty estimation of ± 1% of the IPCC Ym values reflects the fact that diets can alter the proportion of feed energy emitted as enteric methane. Table 8 in Appendix III provides Ym values derived from cattle with diets containing various levels of neutral detergent fibers (NDF). The NDF values of the feed used in the project must be available in order to use Table 8. Detailed information can be found in Appendix III.

	The *IPCC Guidelines for National Greenhouse Gas Inventories* is internationally recognized and the data provided in the guidelines is peer reviewed. Parameters from any source (e.g., IPCC or national agencies) must apply the most conservative value of any uncertainty component. Parameters to be updated each crediting period where new data exists.
Purpose of Data	Calculation of baseline emissions
Comments	N/A

Data / Parameter	NDF_j
Data unit	Dimensionless
Description	Forage quality indices (% Neutral detergent fibers)
Equations	None
Source of data	Records and data from livestock operator or associated partners for three continuous years of historical data prior to the initiation of the project or from national/regional statistical accounts. Records and data during the project implementation also required.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	Data must be provided by the livestock operator or associated partners for each animal group. The assessment of the quality of forages is typically provided by the farmer's nutritionist formulating the rations for the animals. NDF values are used to determine the Ym. Detailed information can be found in appendix III.
Purpose of Data	Calculation of baseline emissions
Comments	N/A

Data / Parameter	ED
Data unit	MJ per kg of dry matter
Description	Energy content of dry matter
Equations	4
Source of data	Default value or farm specific data
Value applied	N/A

Justification of choice of data or description of measurement methods and procedures applied	Farm specific values should be used, when available, otherwise use the typical values provided below: The typical energy density of feedstuff is: - 18.45 MJ kg'$^{-1}$ may be used as a default for diets including edible oils with fat contents in the range of 4 to 6% - 19.10 MJ kg'$^{-1}$ may be used as a default for diets including edible oils with fat contents below 4% Parameters to be updated each crediting period where new data exists.
Purpose of Data	Calculation of baseline emissions
Comments	N/A

Data / Parameter	EC
Data unit	MJ per kg of methane
Description	Energy content of methane
Equations	3
Source of data	Default value taken from IPCC 2006 guidance (Section 10.3.2)
Value applied	55.65
Justification of choice of data or description of measurement methods and procedures applied	This is a standard property of methane. In addition, the *IPCC Guidelines for National Greenhouse Gas Inventories* is internationally recognized and the data provided in the guidelines is peer reviewed. Parameters to be updated each crediting period where new data exists.
Purpose of Data	Calculation of baseline emissions
Comments	N/A

Data / Parameter	$EF_{Enteric\,i,j}$
Data unit	kg CH_4 per animal group
Description	Enteric methane emission factor for each animal group
Equations	1
Source of data	Calculated using equation 2 or 3 or 5
Value applied	N/A
Justification of choice of data or description of	To allow for flexibility for potential projects, this methodology provides different options to calculate baseline emissions.

measurement methods and procedures applied	For option 2 and option 3 the first step in collecting data should be to investigate existing national statistics, national industry sources, research studies and International Environmental Agencies or FAO statistics. National environmental agencies or similar government and research institutions have accurate peer-reviewed data on emission factors or Ym for each animal group. Where no data are available on-site farm measurements can be performed (baseline option 1). The direct enteric methane measurements for ruminants can be conducted using state of the art technologies, well documented in the scientific literature and peer reviewed publications, see examples in table 6 in Appendix II. Parameters from any source (e.g., IPCC, national agencies, or direct measurement) must apply the most conservative value of the uncertainty component. Parameters to be updated each crediting period where new data exists.
Purpose of Data	Calculation of baseline emissions
Comment	Where direct measurements of methane emissions are performed, the project proponent or associated partner must demonstrate experience in methane measurement technologies (i.e., a professional in the area of animal science, livestock health and nutrition who has an M.Sc. or Ph.D. in the relevant discipline).

Data / Parameter	GWP of CH_4
Data unit	tCO_2/tCH_4
Description	Global warming potential of methane
Equations	1,6
Source of data	IPCC defaults
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	The IPCC Guidelines for National Greenhouse Gas Inventories is internationally recognized, and the data provided in the guidelines is peer reviewed. To be updated each crediting period where new data exist or accepted by Verra.
Purpose of Data	Calculation of baseline emissions
Comments	N/A

Data / Parameter:	PE_j
Data unit:	kg CH_4 head^{-1} day^{-1}
Description:	Average project enteric CH_4 emissions calculated by direct measurements using the chosen technology in farm *i* during the monitoring period (kg CH_4 head^{-1} day^{-1})
Equations	7
Source of data:	Measured for each animal group. Data records and study report of farm operations.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	To quantify the project enteric CH_4 an animal sample for each group is selected to perform the direct measurement. The project proponent needs to describe the required sampling protocols against objectives conditions. Sampling protocols should include sufficient numbers and sampling times to account for diurnal and postprandial variation in CH_4. All CH_4 measurement techniques are subject to experimental variation and random errors therefore it should be taken into account when reporting the final enteric CH_4 emission value. Detailed information can be found in appendix II. Parameter to be updated each crediting period or where the PE value is no longer representative (e.g., due to changes in feed regime, animal type, weight, production phase, geographic region, and management practices) new data must be collected.
Purpose of Data	Determination and calculation of project emissions
Comments	Because this requires direct measurements of methane emissions project proponent or associated partner must demonstrate experience in methane measurement technologies (i.e., a professional in the area of animal science, livestock health and nutrition who has an M.Sc. or Ph.D. in the relevant discipline).

Data / Parameter:	$ERF_{Enteric\ j}$
Data unit:	Percentage (dimensionless)
Description:	Enteric emission reduction factor
Equations	6 or 7
Source of data:	Provided by the feed manufacturer for each animal group or calculated using equation 6. Data records and study report of farm operations.
Value applied	N/A

Justification of choice of data or description of measurement methods and procedures applied	For equation 6 the default percentage value is determined from data provided by the feed supplement manufacturer (Option 1). For equation 7 (option 2) the project proponent must provide evidence to demonstrate the percentage enteric CH_4 reduction for each animal group. The project proponent will need to provide during verification the scientific protocol and the results of the measurements. Parameters from the feed manufacturer must apply the most conservative value of the uncertainty component.
Purpose of Data	Determination and calculation of project emissions
Comments	N/A

Data / Parameter:	$EFProduction_{i,j}$
Data unit:	kg CH_4 head^{-1} day^{-1}
Description:	Average project enteric CH_4 emissions calculated by direct measurements using the chosen technology A in farm *i* during the monitoring period (kg CH_4 head^{-1} day^{-1})
Equations	2
Source of data:	Measured for each animal group. Data records and study report of farm operations
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	To quantify the project enteric CH_4 production per animal samples for each group are selected to perform the direct measurement (option 1). The project proponent needs to describe the required sampling protocols for the relevant project conditions. Sampling protocols should include sufficient numbers and sampling times to account for diurnal and postprandial variation in CH_4. In animal studies the most favoured and most scientific method is the calculation of sample size by power analysis (Charan and Kantharia, 2013). All CH_4 measurement techniques are subject to experimental variation and random errors, therefore it should be taken into account when reporting the final enteric CH_4 emission value. Detailed information on reporting such error can be found in Appendix II. Parameter to be updated each crediting period or where the value is no longer representative (e.g., feed regime, animal type, weight, production phase, geographic region, and management practices).
Purpose of Data	Determination and calculation of baseline emissions
Comments	Because this requires direct measurements of methane emissions project proponent or associated partner must demonstrate experience in methane measurement technologies (i.e, at least one team member

	should be a professional in the area of animal science, livestock health and nutrition who has an M.Sc. or Ph.D. and working/research experience in the relevant discipline)

Data / Parameter:	$EF_{i,j}$
Data unit:	kg CH_4 $head^{-1}$
Description:	Average enteric CH_4 emissions factor for each animal in the group *j* during the monitoring period (country or regional specific factors or table 4), (kg CH_4 $head^{-1}$ day^{-1})
Equations	5
Source of data:	Country or regional and population specific factors should be used when available, to better reflect the ruminants' population characteristics. Default values provided in Table 4 may be used as an alternative where regional values are not available.
Value applied	N/A
Justification of choice of data or description of measurement methods and procedures applied	Country or regional specific EF values should be used, when available, to reflect the ruminant's characteristics. When not available, use the default values provided in Table 4. Parameters from any source (e.g., IPCC or national agencies) must apply the most conservative value of the uncertainty component, (i.e., a 50% reduction must be applied to values taken from Table 4) Parameter to be updated each crediting period where new data exists.
Purpose of Data	Determination and calculation of baseline emissions
Comments	N/A

9.2 Data and Parameters Monitored

Data / Parameter:	N_{ij}
Data unit:	Number of animals (head)
Description:	Average number of head in each animal grouping *j* in the farm *i* consuming a supplement during the monitoring period.
Equations	2, 3, 5 and 7
Source of data:	Data records of livestock operations using the feed supplement. Farm records.
Description of measurement methods and procedures to be applied:	Farm inventory data must be calculated as the average number of animals in each grouping, taking into account animal entry and exit movements from the grouping; this is a weighted average approach using the animal head*days factor; an example is demonstrated in the table below.

	<table><tr><td>Days on feed</td><td>Number of head</td></tr><tr><td>1</td><td>100</td></tr><tr><td>2</td><td>100</td></tr><tr><td>3</td><td>103</td></tr><tr><td>Total=3</td><td>Avg=101</td></tr></table>
Frequency of monitoring/recording:	Single value depending on the number of heads in each animal grouping using the natural feed supplement. Measured by daily or weekly average records.
QA/QC procedures to be applied:	Each farm record must list the number of animals in each group. Management and monitoring system to be established by the project proponent at the start of project. It could include data recording and verification procedures.
Purpose of data:	• Calculation of baseline emissions • Calculation of project emissions • Calculation of emission reduction
Calculation method:	No calculations are needed.
Comments:	Monitoring is established at the feed purchaser level. An appropriate and unique identification system for the purchasers, e.g. Project participant name, tax identification number, number of animals in each group, unique invoice number and date, would avoid double counting of emissions reduction claimed. At the time of reporting, baseline and project emissions shall be calculated based on livestock population, climatic conditions and other factors specific to the project and time period.

Data / Parameter:	Days
Data unit:	Days
Description:	Number of days project activity implemented in the specific animal grouping.
Equations	2, 3, 5, and 7
Source of data:	Data records of livestock operations using project feed supplement
Description of measurement methods and procedures to be applied:	None

Frequency of monitoring/recording:	Once for start date of supplement feeding and once for end date of supplement feeding, for each animal grouping
QA/QC procedures to be applied:	Management and quality control system to be established by the project proponent at the start of project. It could include data recording and verification procedures. The number of days could be less than 365. For example, in the case of young cattle the number of days represents the length of stay in a specific animal group.
Purpose of data:	• Calculation of baseline emissions • Calculation of emission reduction
Calculation method:	No calculations are needed
Comments:	N/A

Data / Parameter:	j
Data unit:	Animal grouping
Description:	Animals at each farm *i* should be grouped based on a homogenous ruminant population characterization
Equations	1,2, 3, 5, 6 and 7
Source of data:	Data records of livestock operations using project feed supplement.
Description of measurement methods and procedures to be applied:	Ruminant Population Characterization: Methane emissions from ruminants vary by animal type, weight, production phase (e.g., pregnant or lactating cow), feed type and seasonal conditions. Accounting for these variations in a ruminant population throughout the year is important to accurately characterize annual emissions. Project proponents must provide evidence at each validation and verification that emissions estimates are based on a homogenous population and the herd size and individual animal characteristics remain constant for a given period. Table 10.1 Representative Livestock Categories, in the IPCC 2006 report is an example of detailed characterization required for each livestock species.
Frequency of monitoring/recording:	Once for validation and at least once per monitoring period
QA/QC procedures to be applied:	Management and quality control system to be established by the project proponent at the start of project. It could include data recording and verification procedures.
Purpose of data:	• Calculation of baseline emissions • Calculation of emission reduction
Calculation method:	No calculations are needed

Comments:	N/A

Data / Parameter:	FM
Data unit:	Kg per month
Description:	Amount of feed supplement purchased by the farm *i* during the monitoring period
Equations	8,10
Source of data:	Data records of livestock operations purchasing project feed supplement
Description of measurement methods and procedures to be applied:	Monitoring is established at the feed purchaser level. An appropriate and unique identification system for the purchasers, e.g. Client name, unique invoice number and date, feed purchase receipts, weights, etc. and/or; feed delivery records. Delivery notes and invoices need to be reconciled between buyer and seller to verify records integrity. Sales records should be cross-checked with both buyer and seller of the feed supplemental to make sure records are consistent.
Frequency of monitoring/recording:	Monthly
QA/QC procedures to be applied:	Management and quality control system to be established by the project proponent at the start of project. It could include data recording and verification procedures. Farm records or third-party managed data showing both monthly-purchased complete feed and manufactured complete feed delivered to each grouping
Purpose of data:	Calculation of project emissions
Calculation method:	No calculations are needed
Comments:	Necessary to measure in order to determine monthly volumes of the feed supplement purchased.

Data / Parameter:	EF_P
Data unit:	tCO2e kg^{-1}
Description:	Emission factor for production of feed supplement. GHG emitted per kg of feed. All activities involved at the manufacturer's production facility of the feed supplement.
Equations	9

Source of data:	Records and documentation provided by the feed manufacturer.
Frequency of monitoring/recording:	Monthly
QA/QC procedures to be applied:	These values must be based on well-documented, reliable sources (e.g., national energy balances, government publications, industry associations, WRI/WBCSD GHG Protocol)
Purpose of Data	Determination and calculation of project emissions
Calculation method:	No calculations are needed
Comments	N/A

Data / Parameter:	EF_{T_i}
Data unit:	tCO2
Description:	Emission factor for transportation of feed supplement to the feed mill or directly to the farm *i* during the monitoring period. GHG emitted per kg of feed.
Equations	10
Source of data:	Records and documentation provided by the feed manufacturer.
Frequency of monitoring/recording:	Monthly
QA/QC procedures to be applied:	The project proponent must provide evidence to demonstrate the level of emission the monitoring period. These values must be based on well-documented, reliable sources (e.g., national energy balances, government publications, industry associations, WRI/WBCSD GHG Protocol)
Purpose of Data	Determination and calculation of project emissions
Calculation method:	No calculations are needed
Comments	N/A

Data / Parameter:	Qelec
Data unit:	MWh kg^{-1}
Description:	Quantity of electricity used by production facility supplied by the grid per kg of feed supplement produced
Equations	9

Source of data:	Documentation and date provided by the feed manufacturer
Description of measurement methods and procedures to be applied:	Electric utility bills provided by the manufacturer. For the production of the feed supplement, the monitoring would be for the manufacturer to provide the electricity consumption at the specific production line used for the manufacturing of the monthly quantity. Alternatively, where product line level data is not available the manufacturer can use a ratio based on the percentage the feed supplement represents in the total volume produced by the facility.
Frequency of monitoring/recording:	Monthly
QA/QC procedures to be applied:	To confirm the production of feed supplement monthly production output data need to be available by the manufacturer.
Purpose of data:	Calculation of project emissions
Calculation method:	No calculations are needed
Comments:	N/A

Data / Parameter:	Qff
Data unit:	Volume or kg fuel/kg feed supplement
Description:	Quantity of fossil fuel used (L, m^3 or other of each type of fuel used) at the production facility per kg feed supplement produced.
Equations	9
Source of data:	Report provided by the feed manufacturer
Description of measurement methods and procedures to be applied:	Fossil fuel invoices provided by the manufacturer. For the production of feed supplement, the monitoring would be for the manufacturer to provide the quantity of fossil fuel used at the specific production line for the manufacturing of the monthly quantity. Alternatively, where product line level data is not available the manufacturer can use a ratio based on the percentage the feed supplement represents in the total volume produced by the facility.
Frequency of monitoring/recording:	Monthly
QA/QC procedures to be applied:	To confirm the production of feed supplement monthly production output data need to be available by the manufacturer.
Purpose of data:	Calculation of project emissions
Calculation method:	No calculations are needed
Comments:	N/A

Data / Parameter:	EF_{elec}
Data unit:	kg CO2 MWh^{-1}
Description:	Emission factor for electricity
Equations	9
Source of data:	Country-specific emission factors for grid electricity from a reputable regional or national source. Otherwise from an International organization like the International Energy Agency (IEA).
Description of measurement methods and procedures to be applied:	Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics. Estimation, reference values must be obtained from the relevant national GHG inventory. The value used should be consistent with the source of generation. In the absence of local or regional data, reference values may be obtained from the most recent version of the IPCC guidelines for National Greenhouse Gas Inventories.
Frequency of monitoring/recording:	Annual
QA/QC procedures to be applied:	N/A
Purpose of data:	Calculation of project emissions
Calculation method:	No calculations are needed
Comments	The latest approved versions of CDM tools “Tool to calculate the emission factor for an electricity system” may be used to determine EFelec where country or state/province data are not available. https://cdm.unfccc.int/methodologies/PAmethodologies/tools/am-tool-07-v7.0.pdf

Data / Parameter:	FCa
Data unit:	TJ //volume or kg of fuel
Description:	Energy content per unit of fuel type *a*
Equations	9
Source of data:	Regional or national default values from recognized sources or IPCC reports
Description of measurement methods and procedures to be applied:	Where more than one recognized source is available, the most appropriate source must be selected, based on data quality indicators including technological appropriateness, regional specificity, and vintage of the data.

	These values must be based on well-documented, reliable sources (e.g., national energy balances, government publications, industry associations, WRI/WBCSD GHG Protocol) In the absence of local or regional data, reference values must be obtained from the most recent version of the IPCC guidelines for National Greenhouse Gas Inventories.
Frequency of monitoring/recording:	Annual
QA/QC procedures to be applied:	N/A
Purpose of data:	Calculation of project emissions
Calculation method:	No calculations are needed
Comments	N/A

Data / Parameter:	EF_{fuel}
Data unit:	kg GHG (CO_2, CH_4, N_2O) per L, m^3 or other of each type of fuel used
Description:	Emission factor for fuel combustion type
Equations	9
Source of data:	Regional or national default values from recognized sources or IPCC reports
Description of measurement methods and procedures to be applied:	Where more than one recognized source is available, the most appropriate source must be selected, based on data quality indicators including technological appropriateness, regional specificity, and vintage of the data.
Frequency of monitoring/recording:	Annual
QA/QC procedures to be applied:	Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics. These values must be based on well-documented, reliable sources (e.g., national energy balances, government publications, industry associations, WRI/WBCSD GHG Protocol) In the absence of local or regional data, reference values must be obtained from the most recent version of the IPCC guidelines for National Greenhouse Gas Inventories.
Calculation method:	Calculation of project emissions
Comments	This parameter may be updated over the course of the crediting period (as a project description deviation) due to the availability of more recent information.

Data / Parameter:	TEF
Data unit:	Tonnes per km or miles per kg of feed ($tCO2\ kg^{-1}km^{-1}$)
Description:	Emission factor values for each mode of transport m
Equations	10
Source of data:	Regional or national default values from recognized sources
Description of measurement methods and procedures to be applied:	Default values must be sourced from recognized, credible sources and be geographically and temporally relevant to project specifics. These values must be based on well-documented, reliable sources. The range of appropriate data must be documented and the chosen data must be justified, using criteria that include data source (recognized and authoritative sources); geographic, temporal and technology specificity; conservativeness (i.e., does not overestimate emission reduction); and where the data is peer reviewed (preferred)
Frequency of monitoring/recording:	Monthly
QA/QC procedures to be applied:	Where more than one recognized source is available, the most appropriate source must be selected, based on data quality indicators including technological appropriateness, regional specificity, and vintage of the data.
Purpose of data:	Calculation of project emissions
Calculation method:	No calculations are needed
Comments:	N/A

Data / Parameter:	D_i
Data unit:	Distance unit (e.g. kilometers, miles)
Description:	Total distance travelled by transport mode m for farm i (km or miles)
Equations	10
Source of data:	Data provided by the project proponent or manufacturer
Description of measurement methods and procedures to be applied:	Distance travelled by transport mode m delivering feed supplement consumed during the monitoring period to the project location, farm. Where the feed supplement goes through a feedmill then the distance to the feedmill should be measured and not to the farm.
Frequency of monitoring/recording:	Monthly
QA/QC procedures to be applied:	N/A

Purpose of data:	Calculation of project emissions
Calculation method:	No calculations are needed
Comments:	N/A

9.3 Description of the Monitoring Plan

The project proponent must establish, maintain and apply a monitoring plan and GHG information system that includes criteria and procedures for obtaining, recording, compiling and analyzing data, parameters and other information important for quantifying and reporting GHG emissions. Where measurement and monitoring equipment is used, the project proponent must ensure the equipment is calibrated according to current good practice (e.g., relevant industry standards).

The project proponent must be able to demonstrate the ruminants for which it is claiming emission reductions have been fed with the appropriate quantity of feed supplement. In order to do so, project proponents must provide detailed feeding records as per manufacturer instructions (applicability condition 3c) for each farm as well as proof of purchase of an appropriate quantity of the feed supplement. Proof of purchase may be provided through delivery receipts and invoices, which must contain batch information, or other identification information, that can trace the feed supplement back to the manufacturer.

All necessary documents must be collected and centrally stored by the project proponent, and be available for verification at any time. The data subject to monitoring and required for the determination and further verification must be archived and stored in electronic format by the project proponent for at least two years after initial verification.

APPENDIX I: JUSTIFICATION FOR ACTIVITY METHOD

This initial assessment of activity penetration indicates that there is not enough activity in any country that would put such penetration above the 5% threshold called for in the VCS Program requirements. It is known that no country has an activity penetration rate higher than 5% at this time due to the unique technology availability.

Per the VCS rules, Verra will reassess whether the activity penetration levels remain within the permitted threshold within three years of the initial approval of the methodology. At that time, Verra will base its assessment on national boundaries, focusing on countries where feed supplements that reduce methanogensis have been used. Also, and in the spirit of conservativeness, where sub-national regulations or policies may impact the likelihood of the project activity being implemented, Verra may use such boundaries as the basis of the reassessment of the activity penetration rate.

Positive List

This project activity in particular, and CH_4 enteric fermentation reduction in general, is a relatively recent field with few, if any, fully commercial technologies. Thus, the methodology uses an activity method for demonstrating additionality, with this technology (the natural feed supplement) as the basis for a positive list. This approach stipulates that the total number of ruminants fed with a supplement inhibiting methanogenesis does not amount to five percent of the total number of ruminants in agricultural settings worldwide. Five percent is the activity penetration threshold set by the *VCS Methodology Requirements v4.0*, and is determined by taking the Observed Activity (OA) divided by the Maximum Adoption Potential (MAP). Where the result of this equation is less than five percent, the project activity may be considered additional.

Activity penetration is given as:

$APy = OAy / MAPy$

Where:

APy = Activity penetration of the project activity in year y (percentage)

OAy = Observed adoption of the project activity in year y

$MAPy$ = Maximum adoption potential of the project activity in year y

Maximum adoption potential (MAP) of the project activity in year y

The *VCS Methodology Requirements v4.0* defines MAP as "the total adoption of a project activity that could currently be achieved given current resource availability, technological capability, level of service, implementation potential, total demand, market access and other relevant factors within the methodology's applicable geographically defined market." In this case, given the early stage of feed supplements for reducing enteric methane emissions, it is difficult to say that there are any resource (or other) constraints that would limit the adoption of this technology.

However, for the purposes of this methodology, the maximum adoption potential of this activity may be limited to ruminants that have been reared for the production of meat and dairy products worldwide. The reason for this selection is due to market access and implementation constraints (e.g., necessary infrastructure for getting the feed supplement to the farm, and appropriate facilities to administer the feed supplement to the animal on a regular basis).

The global ruminant livestock population is roughly 3.6 billion[10], of which approximately 2 billion represents the total number of livestock animals used for meat and dairy products. Figure 2 below illustrates the amount of livestock ruminants worldwide11. Table 5 below illustrates the number of livestock animals used for meat and dairy products:

Table 5 Total number of livestock animals used for meat and dairy products

Type of animal	Number of livestock animals
Dairy cattle[12]	278,000,000
Dairy sheep and goat[13]	463,444,034
Cattle for meat production[14]	300,074,797
Sheep, and goat for meat production[15]	989,247,558
TOTAL	2,030,766,389

10 For the purpose of this analysis the ruminant sector comprises cattle, sheep and goat, and buffalo. The global ruminant population in 2010 was estimated to be 3 612 million (FAOSTAT, 2012), with cattle making up nearly 40 percent, sheep and goat 55 percent, and buffalo the remaining 5 percent. (FAO (2017) and https://ourworldindata.org/meat-production#livestock-counts)

11 Data from 1961 onwards is sources from the UN Food and Agricultural Organization (FAO) statistics. Available at: http://www.fao.org/faostat/en/#data/QA

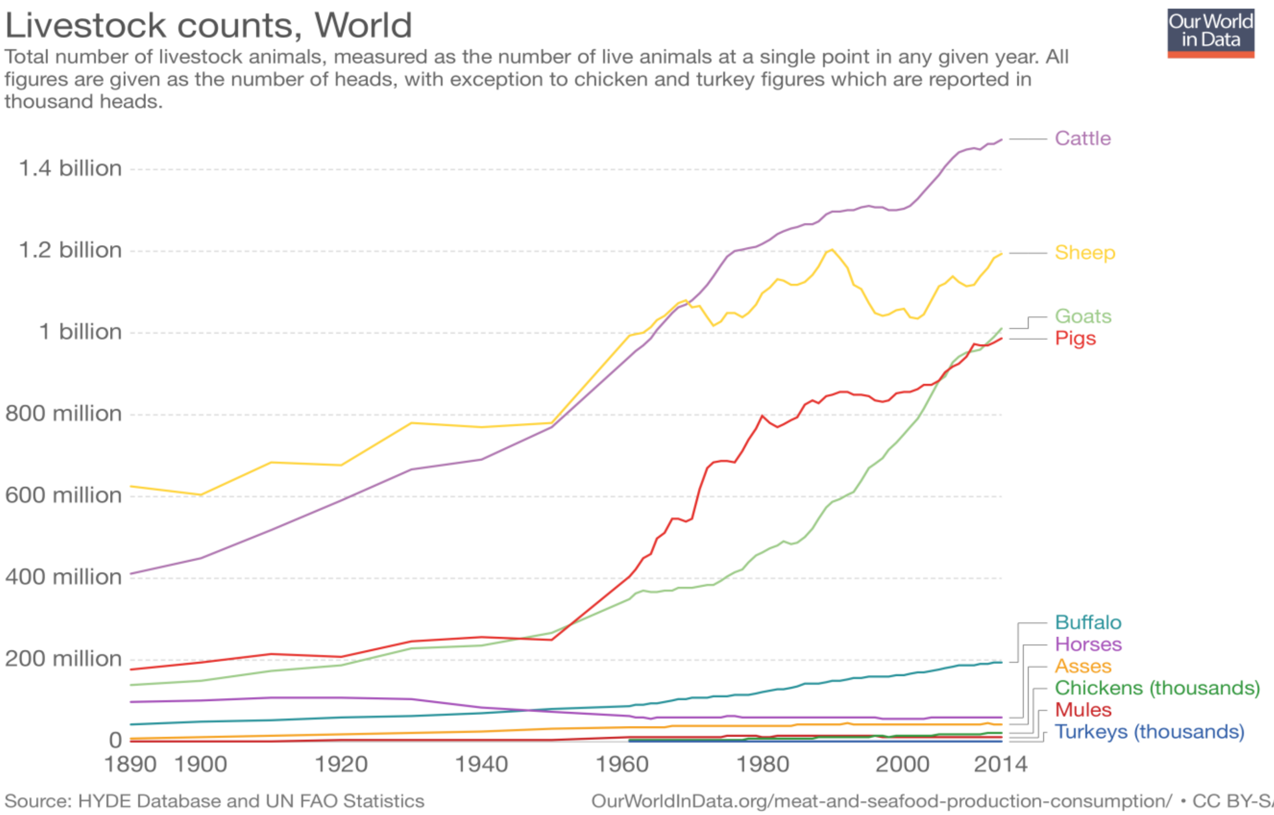
12 https://dairy.ahdb.org.uk/market-information/farming-data/cow-numbers/world-cow-numbers/#.XZxhmS-B2L4

13 Dairy small ruminants account for approximately 21% of all sheep and goats in the world (2'206'876'356 animals, https://ourworldindata.org/meat-production#livestock-counts);

14 Total number of livestock animals slaughtered for meat; FAO (2017) and https://ourworldindata.org/meat-production#number-of-animals-slaughtered-for-meat

15 https://www.sciencedirect.com/science/article/pii/S0022030218305290#targetText=There%20are%20approximately%202%2C200%20million,in%202016%20(799%20Mt)

Figure 2: Total Number of Livestock Animals in The World



According to FAO[16] grazing animals supply about 9 percent of the world's production of beef and about 30 percent of the world's production of sheep and goat meat. In grazing conditions, logistical limitations might occur due to accessibility. Considering that this project activity requires administration of the feed supplement to the animal on a regular basis, grazing animals should be excluded as feeding control cannot be exercised. Dairy animals are not excluded as they can have daily access to the feed in the milking parlour.

Therefore, for the purposes of this methodology, the maximum adoption potential of this activity is limited to MAPy= 1.707 billion.

Observed adoption of the project activity in year y

Few dietary strategies have been proposed to lower methane production in ruminants (Knapp et al, 2014; Boadi et al 2004). However, most of these are not commercially available and/or have no impact

16 http://www.fao.org/3/x5303e/x5303e00.htm#Contents

on enteric fermentation. Currently only a few products have been observed in the market.

Namely, linseed and alfalfa products containing high levels of omega-3 fatty acids can reduce the level of saturated fatty acids, and the elevation of dietary fat levels in ruminant diets may be a suitable way of lowering methane production. From a 2010 report,17 linseed and alfalfa were fed to approximately 50,000 cows. From an article published in 2018,18 a different product consisting of a blend of essential oils that claim to reduce methane production by cattle has reached approximately one million cattle. Neither of these publications report on the reduction of enteric emissions via a reduction of methanogenesis. However, for the purposes of this demonstration of additionality, it is assumed that the project activities are the same. To be conservative it is assumed that the published reports were only capturing half of all enteric emission reduction activities, which results in an estimated activity of 2.1 million ruminants.

Therefore:

APy = *OAy / MAPy*
APy = *2.1 million / 1'707 billion*
APy = *0.123%*
APy < *5%*

Given the current ruminants population and the commercially available feed supplements, and in particular those which have a significant effect on reducing enteric methane emissions by direct inhibition of methanogens in the rumen, it is demonstrated that the activity penetration level of the project activity covered by this methodology is below the five percent threshold, and the project activity may be deemed additional.

Where the project activity has been commercially available in any area of the applicable geographic scope for less than three years (i.e., it uses a new technology or measure), it shall be demonstrated that the project activity faces barriers to its uptake, per the VCS rules. This proposed project activity faces technological barriers that prevent its implementation:

1. The project activity requires extra effort from the farmers to administer the feed supplement as per feeding instructions provided by the manufacturer. In some cases, this might require properly trained farmers to secure the default level of reduction of the enteric methane emissions, such as the feeding routine and dose, to maintain the technology in a way that does not lead to an unacceptably high risk of equipment disrepair and malfunctioning or other underperformance.

17 http://www.pinallet.com/data/FEEEDINFO%20Interviews%20VALOREX%20CEO.pdf

18 https://www.greenoptimistic.com/swiss-company-develops-new-cow-feed-fewer-farts-20181006/#.XF

2. This project activity implementation will require the purchase of feed supplement, which is an addition to the existing farmers' variable costs. Farmers make multiple decisions in the agricultural cycle about the adoption of products and practices. According to Loevinsohn et al. (2013), farmers' decisions about whether and how to adopt new technology are often the result of a comparison of the uncertain benefits of the new invention with the uncertain costs of adopting it. For adoption to occur, farmers need to know that a technology exists, believe that it will improve productivity, and understand how to use it effectively. Given the early stage of feed supplements for reducing enteric methane emissions, farmers willingness to adopt and carry on the activity increase the risk of technological failure due to the process.

3. Natural products occur during a certain time of year (seasonal crops). Therefore, working capital can fluctuate drastically which can lead to an unacceptably high risk of technology availability. Since this methodology is based on natural plant-based technology, the project activity implementation will require management of the seasonal effects on working capital. During the seasonal peak, the company will require higher net investment in short-term (current) assets.

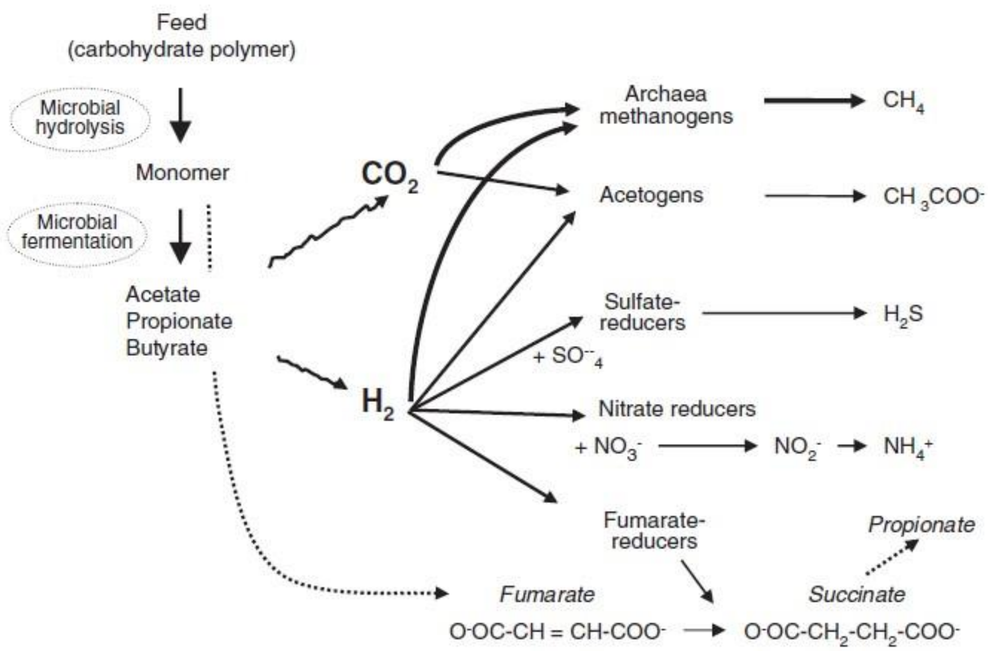
APPENDIX II: BACKGROUND INFORMATION ON PROJECT ACTIVITY

Enteric fermentation is the second largest source of global emissions from livestock supply chains, contributing about 40 percent of total emissions. Cattle emit 77 percent of all enteric methane (Gerber et al., 2013). Ruminants, in particular, release methane as a result of their digestion process of feed material in the rumen. These are enteric emissions from ruminants and are significant contributors to greenhouse gas emissions.

Research on various feed management activities has already been conducted to assess their ability to reduce methane production (Eger et al., 2018). Enteric methane is produced from microbial fermentation of feed (HOBSON et al., 1981; Whitford et al., 2001). Primary anaerobic microbiomes degrade organic matter into volatile fatty acids. In this process, hydrogen gas and carbon dioxide are produced as by-products. Methanogens metabolize hydrogen and carbon dioxide into methane (HEGARTY, 1999; Moss et al., 2000). Figure 1 provides an illustration of the microbial fermentation of feed polysaccharides and H_2 reduction pathways to CH_4 in the rumen.

The production of methane in the rumen can represent a loss of energy up to 12% (Johnson and Johnson, 1995). Therefore, production increases and energy efficiencies by the natural feed supplement could be seen as complementary outcomes when enteric methanogenesis is reduced (Graz et al., 2017). An additional goal of reducing enteric fermentation is to enable livestock producers to improve the environmental profile of meat and dairy products and provide consumers with sustainable climate-friendly products with a quantified carbon footprint reduction.

Figure 3: Schematic microbial fermentation of feed polysaccharides and H_2 reduction pathways to CH_4 in the rumen (Morgavi et al., 2010).



Direct enteric methane measurements

The direct enteric methane measurements for ruminants may be conducted using state of the art methods, well documented in the scientific literature. This includes respiration chambers as an established and widely used technique since 1958. However, some operations require measurements of CH_4 emissions of a larger number of animals, and therefore, short-term measurement techniques such as automated head chambers (e.g., the GreenFeed system) and (handheld) laser CH_4 detection (Hammond et al., 2016) are used to meet this objective with the spot measurement of gas concentrations in samples of exhaled air at certain time points. Repeated spot measurements can be taken whilst the animals are feeding or standing, and during the milking parlour for dairy operations. There are diverse technologies being used worldwide for quantifying enteric methane emission, however, there is no joined-up protocol covering all aspects, including, data collection, data extraction, data handling, and estimating methane volume from the measured concentration. Experience in animal studies is required to develop a protocol to generate accurate results.

In case the manufacturer of the natural feed supplement cannot provide sufficient documentation to support a default emission reduction factor, the project proponent must perform direct enteric methane measurements. The baseline emissions factors may still be set using option 2 or 3 as described in Section 8.1 above. Overall the chosen measurement technology and the measuring procedures must meet the following conditions:

1. The technology must be well documented in the scientific literature in peer-reviewed publications.

2. The technology enables measurements for animals in their 'normal' environment, which can be applied under conditions relevant to project livestock production.

3. The measurement error of the technology and sample error needs to be reported under the project conditions.

4. The project proponent or associated partner need to demonstrate technical skills and experience in operating direct enteric methane measurements to generate accurate results

5. The recommended measurement protocol needs to determine optimal sample size and recording duration.

6. The project proponent shall estimate the measurement uncertainty and apply confidence deductions to reduce bias and uncertainties as far as is practical. Methods used for estimating uncertainty shall be based on recognized statistical approaches such as those described in the *IPCC Good Practice Guidance and Uncertainty Management in National Greenhouse Gas Inventories*. Confidence deductions shall be applied using conservative factors such as those specified in the *CDM Meth Panel guidance on addressing uncertainty in its Thirty Second Meeting Report, Annex* 14

Table 6 provides a description of three different technologies for direct measurement of enteric methane emissions and, therefore, calculate the emission reductions following a specific scientific protocol. These three technologies are used for demonstration purposes and are not restrictive, as improving technologies could allow more accurate measurements in the future.

Table 6: Measurement technologies of enteric methane emissions

Type of measurement method/technology	Description of the method/technology
Respiration Chambers	Respiration chambers are used to measure CH_4 at an individual animal level under research conditions. The principle of the respiration chamber is to collect exhaled CH_4 emissions from all sources of enteric fermentation (mouth, nostrils and rectum) from the animal and measure the concentration. The cow needs to be in the chamber up to 4 days. All open-circuit chambers are characterized by an air inlet and exhaust fans. Each chamber is fitted with internal ventilation fans for efficient mixing of expired gases and incoming gases. The chamber is equipped with sensors for measuring relative humidity, temperature, barometric pressure and gas (CH_4, H_2, O_2, H_2S).
Automated head chambers – Infra-red method for methane measurements (e.g., GreenFeed – Large Animals)	Short-term CH_4 emissions can be measured by automated head chambers. One such device is the GreenFeed (GF) system (C-Lock Inc., Rapid City, South Dakota, USA). The GreenFeed (GF) system is a static short-term measurement device that measures CH_4 (and other gases including CO_2) emissions from individual ruminant by integrating measurements of airflow, gas concentration, and detection of head position during each animal's visit to the unit (Zimmerman and Zimmerman, 2012).

Laser system for methane detection (LMD)	A handheld methane detector (LMD) is a tool for estimating the methane emissions from individual ruminants by measuring the profiles of the exhaled air. The method uses laser absorption spectroscopy to measure the methane concentration (ppm-m) in a distance of one meter, between the hand-portable instrument and the solid target (cow's nostrils). The analysis is based on real-time breath analysis. The measurement time depends on the natural fluctuation, which arises around once in three minutes (Chagunda et al., 2013).

APPENDIX III: Y_M PERCENTAGE OF GROSS ENERGY IN FEED CONVERTED TO METHANE FOR A SPECIFIC ANIMAL GROUP

The Ym value is defined as the percentage of gross energy intake by the ruminant that is converted to methane in the rumen. As mentioned in section 9 for Ym, national environmental agencies or similar government and research institutions have accurate peer-reviewed studies that provide Ym values.

In the IPCC guidelines (1996) default values for the CH_4 conversion rates are provided for the different animal categories when no respective values are available from country-specific research (table 7). These estimates are based on the general feed characteristics and production practices found in either developed or developing countries. The associated uncertainty estimation of ± 1% of the Ym values reflects the fact that diets can alter the proportion of feed energy emitted as enteric methane. When the quality of the feed is good the lower bounds should be used (i.e., high digestibly and energy value). Higher bounds are more appropriate when poorer quality of feed is available. Neutral detergent fiber (NDF) is often considered a good determinant of quality. NDF measures total cell wall content of plant and indicates maturity; the higher the value, the more mature and lower quality the forage.

Table 7:Livestock CH_4 Conversion Factors[19,20]

Livestock category	Ym 21
Feedlot fed Cattle 22	3.0% ± 1.0%
Dairy Cows (Cattle and Buffalo) and their young	6.5% ±1.0%

19 When the quality of the feed is high the lower bounds should be used (i.e., high digestibly and energy value). Higher bounds are more appropriate when poorer quality of feed is available. The neutral detergent fiber (NDF) provides information to the quality of the feed. NDF within a given feed regime is a good measure of feed quality and plant maturity. For legume forages, NDF content below 40% would be considered high quality, while above 50% would be considered poor. For grass forages, NDF < 50% would be considered high quality and > 60% as low quality.

20 Note that in some cases, CH_4 conversion factors may not exist for specific livestock types. In these instances, CH_4 conversion factors from the reported livestock that most closely resembles those livestock types can be reported. For example, CH_4 conversion factors for other cattle or buffalo could be applied to estimate an emission factor for camels.

21 The methane conversion factor ± values represent the range.

22 When fed diets contain 90 percent or more concentrates

Other Cattle and Buffaloes that are primarily fed low quality crop residues and by- products	6.5% ±1.0%
Other Cattle or Buffalo – grazing	6.5% ± 1.0%
Lambs (<1 year old)	4.5% ± 1.0%
Mature Sheep	6.5% ± 1.0%
Source: 2006 IPCC Guidelines for National Greenhouse Gas Inventories, Volume 4, Chapter 10, table 10.12 and table 10.13.	

The following Table 8 may be used (as an alternative to Table 7) to estimate Ym. The values of the table are derived from cattle with diets containing various levels of NDF. The NDF values of the feed used in the project must be available in order to use Table 8.

Table 8: Estimates of the Percentage of Gross Energy in Feed Converted to Methane (Ym) for Various Diets (Grainger and Beauchemin, 2011 and Moate et al. 2011)

Various Diets	Ym (% of GEI)
Default (unknown diet composition)	6.50%
Diet with < 25% NDF	5.50%
Diet with 25-30% NDF	6.25%
Diet with 30-50% NDF	6.50%
Diet with >50% NDF	7%
Situations in which adjustments apply to YM values above*	
Feeding fats*	
Calcium salts of palm oil (or similar bypass fats)	No reduction
Other Fat Sources*, not to exceed 80 g fat/kg DM . Reduction of Ym for each 10g increase in fat content per kg of animal feed on a dry matter basis (10g fat/kg DMdiet)	-3.40%
*Corn DDGS cannot exceed 20% of dry matter of ration, and the higher protein content of the DDGS must be addressed in the ration formulation to prevent excess nitrogen excretion. The procedures to implement proper use of lipids and corn DDGS must be documented by the nutritionist Source: Alberta Offset System: Quantification protocol for reducing greenhouse gas emissions from fed cattle
